Dr. D. N. NABARRO said that the pneumococcus was an organism whose pathogenicity was strikingly variable in different animals. In some it produced a rapidly fatal septicaemia, whilst others were immune. Man occupied an intermediate position, and pneumococcal infections were usually localized. Children, however, were more susceptible than adults, and in them a generalized infection of serous cavities was not very uncommon. Primary pneumococcal peritonitis was, so far as the records of Great Ormond Street Hospital showed, a rare disease. Only fifteen cases had been diagnosed since 1918, and only seven of these had grown pneumococcus from the exudate. Of the fifteen cases diagnosed as pneumococcal peritonitis, five recovered and ten died; all were females. Macartney and Fraser, in their paper on this subject, described the recovery of the same pneumococcus from the pus in the pelvis, the blood, and serous cases yielded an organism which was morphologically a pneumococcus, but as no bile solubility or pathogenicity tests had been performed, it was possible that the organism

was a variety of streptococcus—for example, that sometimes described as the enterococcus. In the case of a female child aged 16 months, diagnosed as pneumococcal peritonitis, the organisms isolated from the pus were *B. coli* and streptococcus; the same organisms were recovered from the vagina. He thought it probable, therefore, that many cases, which clinically were diagnosed as pneumococcal peritonitis, were due to another organism. Macartney and Fraser, in discussing the etiology of this disease, pointed out that its incidence was limited to female children, generally of the poorer classes who were apt to sit about without protection for the perineum, so that they contracted a vulvo-vaginitis. As a result the vaginal secretion was not acid as in health, so that the pneumococcus was able to flourish, and eventually to make its way into the abdomen via the genital tract and tubes. These authors pointed out that the pneumococcus was recoverable from the vagina in every case, that the first symptoms were those of subumbilical peritonitis, and that at laparotomy, in early cases, pus was found in the pelvis only. They had reproduced the disease in a female monkey by introducing the pneumococcus into the vagina after it had been rendered alkaline by washing out with a solution of sodium bicarbonate. The only alternative routes by which the pneumococcus might gain entry into the peritoneal cavity—namely, by the blood stream or through the intestine—were apparently negatived by the fact that all the cases occurred in females. Dr. Nabarro suggested that the milder cases, which recovered without operation, and from which in consequence no pathological material was available, were cases of enterococcal and not pneumococcal peritonitis, since the enterococcus was more commonly found in the accompanying

The CHAIRMAN (Dr. Thursfield) commented upon the curious geographical distribution of the disease, which was apparently common in Edinburgh, and commoner at Guy's Hospital than in North London. He had himself never seen a case which he could diagnose with certainty.

Mr. R. A. RAMSAY pointed out that the acute cases were almost invariably confused with appendicitis. The diagnosis could easily be made at operation by the absence of smell from the pus. In his experience the mortality of acute cases was very high, and operation did not help. His one recovery from the acute stage had occurred after putting Type I pneumococcal serum into the drainage tube, but he did not know whether recovery was attributable to this. A child first seen in the "residual abscess" stage had recovered after a number of metastatic abscesses in the limbs and elsewhere had been opened.

Dr. ERIC BELLINGHAM SMITH had seen eight cases, seven of them in girls, but one in a boy. The ages of the patients ranged between 3 months and 8 years. Diarrhoea occurred as a premonitory symptom in all cases. He disagreed with Mr. Waugh as to the absence of pain, for in the cases which he had seen there was acute pain and tenderness throughout the illness. Only three of these cases had recovered. In his experience operation, while justifiable and necessary in the residual abscess stage, was totally unjustifiable in the acute stage. He quoted a case in which operation was performed on the fourth day, when there were signs that the toxæmia was diminishing, on account of persistent tenderness in the right iliac fossa; the child was dead within twenty-four hours. He considered that the only chance for the patient lay in expectant treatment in the Fowler position until such time as a residual abscess should have formed.

Mr. MAX PAGE did not think the mere drainage of the abdomen in the acute stage was in any way helpful, an abscess stage provided he could be certain of the residual condition in the acute stages.

Mr. E. C. HUGHES was convinced of the futility of operating in the early stage, and would never do so provided appendicitis could be definitely ruled out; many cases were, however, indistinguishable. In the differential diagnosis the general distension of the abdomen or the appearance of a swelling at the umbilicus were helpful signs.

Mr. J. McLEAN PINKERTON had seen five cases of this condition during two years as a resident at a small hospital

in South London. Three of the cases were proved to be pneumococcal peritonitis by pathological examination, and though the pus was not examined in the other cases there could hardly be any doubt as to the diagnosis. The clinical course and the appearances at operation of the cases coincided with that described by Mr. Waugh. Two had been operated upon in the acute stage and the others in the residual abscess stage, and all recovered, although one of the cases operated upon in the acute stage had required a further operation for a residual abscess in the pelvis.

Mr. J. A. C. FORSTH had seen a few cases, all of which resembled those described by Mr. Waugh. In one case—a girl, aged 8 years, who had exhibited prodromal diarrhoea—ho had operated at an early stage on account of slight tenderness in the right iliac fossa. At the operation the appendix and caecum were found to be normal, but the tubes were crimson. He drained the abdomen and left the tubes intact, although he was somewhat doubtful as to the wisdom of doing so. The girl recovered at the time, but had recently undergone an operation at the hands of another surgeon for double pyosalpinx. He considered that the absence of rigidity was one of the striking features of pneumococcal peritonitis.

Dr. ROBERT HUTCHINSON commented upon the lack of unanimity amongst the speakers as regards both diagnosis and treatment; and Dr. CAMERON and Dr. NANNING replied briefly.

### TREATMENT OF PULPLESS TEETH.

At a meeting of the Section of Odontology of the Royal Society of Medicine on January 26th, Mr. J. G. TURNER presiding, two papers were read on the subject of pulpless teeth.

The first was a communication by Mr. CALE MATTHEWS, who described a case of long-standing insomnia treated by the extraction of these teeth. The patient was a married woman aged 44. She had marked exophthalmos, but no goitre, and otherwise was in excellent health. In May, 1923, she had an intermittent temperature after pneumonia, and the doctor attending her thought that the temperature might be due to some other cause, and advised that her teeth be radiographed. It was then elicited that she had been suffering from a gradually progressing insomnia during the previous twenty years. Her average night's sleep was three or four hours, and if there was any worry or domestic disturbance she got no sleep at all. More than twenty years previously—before the insomnia began—she had certain root fillings and crowns. After an investigation of the radiographic result it was decided to remove all the pulpless teeth. The extraction proved extremely difficult, and for two or three subsequent days the patient was very much distressed, but four or five nights afterwards she had the best night's sleep she had had for years, and this improvement continued. Almost a year afterwards her healthy and rejuvenated appearance made her almost unrecognizable as the same woman; she was sleeping well, and, most notable of all, there was a total disappearance of the exophthalmos. At first the speaker was inclined to think that the improvement might be a temporary one, due to some psychic cause, but it persisted. He could offer no explanation except that the removal of the septic foci eliminated the cause of the hyperthyroidism which might have been the determining factor of the insomnia.

Mr. J. G. TURNER said that in his own experience he had found that insomnia was one of the things which might be cured by clearing out a mouthful of foul teeth, whether dead or subject to pyorrhoea. Only the previous week, by taking out one loose pyorrhoeic tooth, he had restored sleep to a patient who had been clamouring for drugs.

Mr. L. E. CLAREMONT read the second paper, on the general aspects of the problem of pulpless teeth. After a description of the anatomy and pathology of the parts concerned, he went on to speak of treatment, confining his remarks to the permanent dentition. The treatment of deciduous pulps was impracticable, except perhaps in permanent teeth could be considered under three headings: (1) devitalization of the living pulp; (2) cleaning and filling of sterile canals; (3) treatment of septic teeth. The rule,

"When in doubt, remove the pulp," was, he considered, a good one. The development of infection during treatment was a very important thing to be guarded against, and a thing liable to be forgotten. Everything that came in contact with a tooth under treatment was infectious and a certain source of infection unless sterilized. In cleaning and filling the canals the watchword should be "sterility." It was not possible to be aseptic, but the next best thing could be done—namely, the work could be carried out in an antiseptic atmosphere. The choice of antiseptic was limited. Tricresol was the nearest approach to the ideal. The teeth should be isolated with rubber wiped over with tricresol. All instruments should lie in tricresol. A tooth should be allowed to drain, and the canal contents should afterwards be rendered sterile, before removal. Secondary dentine or pulp stones might be absorbed out by means of sulphuric or hydrochloric acid. The use of mummificatory paste should be restricted as much as possible; he viewed it with great distrust. Various methods had been devised for filling the canals. If gutta-percha points were used they should always be kept in formalin vapour and taken straight from this to the canal. The treatment of teeth already infected was the greatest problem before the dental surgeon of to-day. The first thing to do was to arrive at a correct diagnosis. Errors were frequently made through want of co-ordination of the factors and misinterpretation of the x-ray photographs. Mr. Claremont dealt first with treatment via the pulp canal, and secondly with surgical treatment. With regard to the pulp canal, the great question was whether it was possible to render the periapical area and the sinus, if present, sterile. Systemic toxæmia arising from apical sepsis had been conclusively proved. Before commencing treatment via the pulp canal one should consider the age of the patient and the question whether there was any systemic infection present. Ionization, using a solution of zinc chloride, with the positive pole so that chlorine was given off in the canal, was constantly used. His misgiving was whether all the organisms present in a spongy apex and beyond it had been killed. The apex was frequently necrotic, and it seemed almost impossible to prevent such a condition from being the source of further mischief. Sinuses might arise in two ways—from the bursting of an acute apical abscess and from a chronic abscess. Theoretically the teeth in which sinuses had developed would appear to offer more satisfactory scope for rendering the periapical tissue sterile. But whatever kind of treatment was carried out around the pulp canal left a feeling of dissatisfaction on the part of the operator. Surgical treatment might be considered as (1) preliminary sterilization and filling of the root canal, followed by removal of the diseased periapical tissue; (2) preliminary sterilization and filling of the root canal, followed by removal of the necrotic apex and the surrounding tissue (this, provided the patient was healthy, might be applied to the upper incisors, canines, premolars, and possibly the lower incisors, with apical rarefied areas involving not more than one-fourth of the periodontal membrane); (3) extraction coupled with curettage (it was most important to eurette thoroughly the apical region of the tooth sockets after extraction). Cases suitable for this last procedure were those involving the upper molars and most of the lower teeth, with large areas of destruction, and teeth with a sinus opening into the antrum, nasal fossa, or on to the skin.

In the course of general discussion, Mr. LIVINGSTON remarked that formalin vapour for the sterilization of instruments was practically useless, especially in a dry cabinet. He obtained perfect sterilization of gutta-percha by using absolute alcohol to which was added about 40 per cent. formalin. Mr. SPRAWSON said that it had always seemed to him difficult to know when the pulp canal was sterile, and he thought it would be rather useful to test by films and cultures a number of teeth after they had been carefully dressed. Mr. CALE MATTHEWS said that the technique of the treatment of pulpless teeth was very exacting to the general practitioner of dentistry. He wished the reader of the paper had said something about the ammoniated silver nitrate method of root filling. If the radiograph meant anything to them, it was a great satisfaction to study the radiographic appearance of teeth after they had been filled with the silver nitrate. Mr. SKINNER

thought it most important that the patient should be warned that once he had a dead tooth in his head, sooner or later trouble might arise.

Mr. A. T. PIRTS asked whether there was any greater likelihood of apical rarefaction developing in teeth which had been devitalized and afterwards had become infected than in a tooth which had died what he might call a natural death and had not been treated at all. There was an impression amongst medical men that apical rarefaction was always the sequel to dental treatment, and dental technique was regarded as being on its trial. The physician saw various teeth with obvious fillings and crowns, and, noticing apical rarefaction, came to the conclusion that the condition was due to the dentist. He would like a series of radiographs to be taken on patients with entirely neglected mouths, which he believed it would be found that apical rarefaction was quite common.

Mr. J. G. TURNER closed the discussion by remarking that the question of the depth of infection of the dentine had been overlooked, and that until this had been dealt with one was still left, whatever might have been done, with an infective dead piece of tissue.

### MENTAL SEQUELAE OF ENCEPHALITIS LETHARGICA.

THE discussion on "The mental sequelae of encephalitis lethargica" at the Royal Society of Medicine (see *BRITISH MEDICAL JOURNAL*, January 17th, p. 114) was resumed on January 27th. Dr. R. H. COLE, Vice-President of the Section of Psychiatry, was in the chair.

Dr. J. C. SKEENE (Newcastle) dealt with the subject as it concerns children, for 30 to 40 per cent. of the cases of the disease he had seen were under 12 years of age. He considered that the chief problem was not so much diagnosis, or even treatment—the latter being so ineffective—as prognosis. It was very difficult to foretell, in any given case, what the ultimate mental condition of the patient would be. Even in cases having a mild initial attack the later mental changes might be quite gross. One of the most important results of the disease, he found, was a diminution or perversion of volition; the patient might remain motionless for hours. He described the types of cases he had met with, and quoted illustrative examples of each.

Dr. C. WORSTER-DROUGHT stated that cases of mental disorder reaching certifiable limits were comparatively rare. When they did occur the condition was either progressive dementia, a delusional state, or hallucinatory confusion. He did not think it could be said that there were any really characteristic mental symptoms arising from encephalitis lethargica; perhaps the most frequent was an apparent apathy, but tests showed this was not really so pronounced as it appeared to be, and there was but little impairment of intellect. In most of the 19 cases tested by Dr. Harncastle and himself the psycho-motor reaction time was definitely lengthened, usually by about 50 per cent., but the cerebration time was not appreciably altered. In the general intelligence tests only 3 of the 19 were below the normal, the deficiency in those 3 being chiefly in the regions of memory and reason. The prognosis in regard to moral deterioration following the disease was often quite good.

Dr. HARNCASTLE expressed his agreement with the remarks of the previous speaker. In some of the cases inquired into, he said, the onset of the symptoms was preceded by an extraordinary sense of well-being. Some cases seemed to recover completely, and then, perhaps six months later, mental sequelae became definitely established.

Dr. E. MAROTER mentioned the results of his investigations in 45 cases of the condition which had been received into the Maudsley Hospital. Those cases could be arranged under three headings: (1) mental anergia, (2) morbid restlessness, (3) demoralization. The occurrence of extreme lethargy seemed, generally, to be ominous as regards the subject's future. In many cases showing mental changes the initial illness was so slight that its nature had not been recognized. There seemed to be no relation between the organic and the mental changes. In the majority the disturbances were consecutive. There was a marked spontaneous variation, suggesting an active continuance of the disease.

Many of the cases obviously needed institutional treatment, either because they were incapable of self-support or because they were a nuisance to others.

Dr. GRAHAM FORBES spoke of some cases in which the mental after-effects of encephalitis lethargica were complicated by epilepsy, and in some instances it had not been possible to determine whether the condition the patient was found in was post-epileptic or post-encephalitic.

Dr. J. GILHOVEN referred to some adult cases in which, after apparent recovery, the patients developed mental conditions such as defective memory, restlessness, and dementia four or more years after the initial attack.

Dr. CRICHTON MILLER said that for the mental symptoms following the Parkinsonian type of the disease, sedative drugs, especially hyoscin, seemed to have a specific effect on the apathy and the anergia.

Dr. WORSTER-DROUGHT said that if once hyoscin was started in these cases it was difficult to leave it off, and for that reason he was very chary about giving it.

Dr. P. C. P. CLOAKE spoke of the relationship of psychic trauma to the onset of this disease. In one case it followed immediately upon the boy being pushed into a bath strongly against his will. He thought it likely that the disease was at least aggravated by such trauma. The findings of Dr. Worster-Drought and his colleague in regard to psycho-motor retardation did not agree with those of Narval and others. But there was a psychic retardation apart from the execution of motor acts. With regard to the period of abstinence from school, he advised that the subjects of the disease should be kept from school considerably longer than would otherwise appear to be necessary. Finally, he considered that the essential feature of the psychic change was the result of a definite organic injury to the cerebral cortex, this injury being caused by the toxin of the disease.

The CHAIRMAN (Dr. Cole) said he considered the disease only mildly infective, but he related a few cases in which there seemed to have been conveyance from one to another; in one the nurse and matron concerned with a case both had the disease afterwards. These might be coincidences, and the cases might each have derived the virus from the same source, rather than from each other. Hyoscin was a drug which should not be used for any length of time; it should be looked upon only as a drug for emergencies. Patients who had recovered from mental illness and to whom this drug was given told him that they felt as if they were in a vice; they had the desire to move, but were unable to do so.

### THE WASSERMANN REACTION AS AN INDICATOR IN THE TREATMENT OF SYPHILIS.

At a meeting of the Liverpool Medical Institution on January 15th, Professor ERNEST GLENN, Dr. R. E. ROBERTS, and Dr. PHOEBE BIGLAND, in a paper entitled "The failure of mercurial continuation treatment to keep a negative Wassermann negative in syphilitic out-patients," communicated the second half of their study of the Wassermann reaction in relation to the treatment at Dr. F. P. Wilson's clinic at the Royal Infirmary. A report of the first half of this study appeared in the *JOURNAL* of April 26th, 1924 (p. 748).

The authors studied the Wassermann relapse incidence in 503 patients whose reaction was negative after the standard admission course of six doses of salvarsan, etc., and eight of intramuscular grey oils. About two-thirds of these patients received continuation courses of either grey oil or mercury tablets—the latter usually prescribed to sailors or other "wanderers"—to keep their Wassermann reaction negative. About one-third received no treatment for a few or many months because of their irregular attendance. The authors were therefore able to compare the Wassermann relapse incidence in the three groups. The patients were divided into five periods dating from the beginning of their negative Wassermann—namely, 0 to 6 months, 503 patients; 7 to 12 months, 382 patients; 13 to 24 months, 264 patients; 25 to 36 months, 100 patients; 37 to 48 months, 27 patients. Among these there were 185 "first" Wassermann relapses; six cases of reinfection were excluded. The Wassermann relapses were classified into complete and partial, the technique being number 4 of the

## INTERNATIONAL HEALTH ACTIVITIES.

At a meeting of the Medico-Legal Society on January 20th Mr. F. LLEWELLYN JONES (coroner for Flintshire) read a paper entitled "The law of nations and the health of nations—a survey of international health activities before and after the great war."

He said it was only in comparatively recent times that the State had concerned itself with matters of public health. Questions of sanitation had not received the attention of the Legislature to any appreciable extent up to the middle years of the last century, and it was only under the stimulus of men like Sir John Simon, the chief medical officer to the Privy Council, that a code of laws to regulate public health ultimately found its way on to the statute book. Consequently, it was scarcely to be wondered at that health was not regarded as a subject of international control. The law of nations did not embrace questions of international health, and it was not until 1823 that the first international scientific conference was held. The close of the recent war marked the beginning of a new era, and the developments which had taken place since the formation of the Covenant of the League of Nations provided for the creation of an organization for the international control of health. Mr. Llewellyn Jones referred to the first English Quarantine Act, of 1710, and to the cholera epidemic of 1849-50, which led to a scientific inquiry resulting in the adoption of a policy of the almost total abolition of quarantine, though he pointed out that the Quarantine Act was not repealed until the passing of the Public Health Act of 1896, which transferred from the Privy Council to the Local Government Board the power to deal with ships infected with plague or yellow fever arriving in British ports, the great Act of 1875 having already transferred such power to deal with cholera. The International Health Office, which was eventually transformed into the International Office of Public Hygiene, grew out of the deliberations of the International Health Conference of 1903, but it was not until the Covenant of the League of Nations was framed that there was any extensive provision for the exercise of international health functions by a body representative of the different nations of the earth. At the first meeting of the League in Paris in 1920 the International Health Organization was established, and he was of opinion that there was no department of the League's activities which could claim so much successful work. The great war had resulted in famine in Eastern Europe and an epidemic in Russia, and the League appointed an Epidemic Commission in 1921, which undertook the organization of quarantine stations, the equipment of hospitals, the supplying of food and other necessities, and the providing of measures for disinfecting and cleansing. This was the first attempt to deal internationally with an epidemic on a large scale, and the work of the Commission met with a great measure of success. The Health Organization had also initiated the step of interchanging public health personnel, by which sanitary officers became acquainted with practical solutions of public health problems, as well as with the organization of public health services, in various countries. The service of epidemiological intelligence and public health statistics had been most useful, reports on the prevalence of notifiable diseases being transmitted regularly from practically all the countries of the world. The health staff at Geneva had undertaken the supply of official vital statistics and statistical procedure, and were collecting information as to legislation and procedure regarding registration of births and deaths, certification of causes of death, notification of diseases, and other matters. The work of this department was of considerable value and interest to those engaged in public health administration. Therefore it was clear that there was a growing recognition of the importance of co-operation between the nations on sanitary matters, especially since the great war. The League had stemmed the spread of cholera and typhus in Eastern Europe, and research was being encouraged. Indeed, it was gratifying to the friends of international peace to know that, although eminent scientists were still searching for instruments and agencies of destruction for use in future wars, there were in all lands men who were

engaged in a campaign against the scourges and enemies of the human race.

In the discussion which followed the Chairman (Mr. Walter C. Williams) observed that the work of their Health Department was of especial value to those members of the legal profession who were engaged in carrying out parliamentary enactments for the prevention and cure of disease.

## Reviews.

## ACUTE POLIOMYELITIS.

THE history of the early epidemics of diseases which have been carefully recorded by competent observers are always fruitful objects of study. The volume *Infantile Paralysis in Vermont*,<sup>1</sup> dealing with the various epidemics in the State between the years 1894 and 1922, is dedicated to the memory of Dr. Charles S. Caverley, whose pioneer work in the investigation of the disease as it occurred there between 1894 and 1917 has amply earned this graceful recognition. Seven of his original papers and reports on the subject are here reprinted. It appears that the first epidemic of poliomyelitis of any extent in the United States was that in the State of Vermont in 1894. Dr. Caverley's account of this will well repay study, especially when it is remembered how great has been the increase in knowledge of the subject since that time; indeed, the reader will easily appreciate this when he reads that two well known neurologists expressed the opinion that the disease was cerebro-spinal meningitis.

Since then Vermont has earned an unenviable notoriety in the matter of the incidence of the disease, other epidemics having taken place in 1910, 1911, 1912, 1914, 1915, 1916, and 1917. The reports of these abound in details of epidemiological and clinical importance, which reflect the industry and the skill of the observers. That dealing with the severe outbreak of 1914 may be selected as especially full of interest and information. That the principal seasonal incidence of the disease should be in August, September, and October agrees with the majority of experiences elsewhere; but the statement made that in Vermont it seems to be a rural as opposed to an urban disease conflicts with much other experience, notably, indeed, that in regard to the city of New York.

It is interesting to read the regulations adopted by the Vermont State Board of Health in 1916 in regard to the attendance of children under 15 at public gatherings; would public opinion here consent to their exclusion from all fairs, cinemas, theatres, schools, and churches, even in the presence of an epidemic of poliomyelitis? In 1917 the local board of health of Barre, Vermont, went so far as actually to prohibit all public gatherings of any kind, and we are informed that the city of Barre enjoyed comparative immunity from the disease. Our own health authorities must surely look with envy on the drastic powers employed by the Vermont Board of Health.

The after-treatment of the residual paralysis was placed under the direction of Dr. R. W. Lovett, professor of orthopaedic surgery at Harvard Medical School, whose untimely death is much deplored. Through his organization a very large number of cases were kept under observation and treatment. A quantitative test of muscle power, especially of the power of different groups of muscles or movements, was devised by means of a spring balance; its design and use are illustrated by plates. There is nothing very new in the description of the methods of after-treatment employed, but emphasis is laid on the value of muscle training. The use of diathermy is not mentioned.

Included in the volume are chapters describing the experimental results obtained with nasal washings from cases of the disease, but since much of this work has been repeated and extended in more recent years this section loses much of its interest. The book concludes with two chapters on the treatment of acute poliomyelitis by means of the intra-

<sup>1</sup> *Infantile Paralysis in Vermont, 1894-1922*. Burlington, Vermont: State Department of Public Health, 1924.

venous injection of hypertonic saline solution and the intrathecal injection of serum from convalescents. The epidemiologist and the neurologist will find in it much to interest them.

### LIFE INSURANCE EXAMINATION.

Dr. F. W. Foxworth has got together a band of forty-nine contributors to the volume, *Life Insurance Examination*,<sup>2</sup> he has edited. His claims that it will prove both a guide and a text book to the medical examiner seem to be well justified. It surveys briefly the history of life insurance, industrial insurance, group insurance, fraternal insurance, and friendly societies, and sketches the comparatively recent origin and development of medical examination for life insurance, which dates back only to the middle of last century. Interesting chapters are devoted to the relation that should exist between medical examiners and agents, whose interests may often tend to conflict, and also to the close co-operation that should be maintained between the medical examiner and the actuary. The organization and administration of the medical department in American life offices is fully described, and the functions and duties of medical directors at the head office, of the medical referees supervising various "territories," and of the medical examiners in individual towns or districts, are explained. The training of medical officers for life-office work appears to be advancing generally along specialized lines towards the development of the particular viewpoint necessary for the medical examiner. While diagnosis is important, prognosis is still more so, and must be specialized in order that it may be translated into such terms that the degree of extra risk can be assessed under special mortality tables. An appreciation of the incidence of mortality is also shown to be of great importance. In short, the medical examiner and the actuary must be closely associated, so that their co-operation in the assessment of risks, expressed in terms of monetary equivalents, may be soundly based on the statistics prepared by the joint labours of the clinician and statistician. Such statistics are abundant in this work, more particularly in connexion with gastric and duodenal ulcers, blood pressure, goitre, neoplasms, glycosuria, and post-operative and tropical risks. These statistics and practical conclusions drawn from them are worthy of the careful attention of all British medical examiners and actuaries. The nature of post-operative risks is also examined, and the methods of treating them for life insurance are concisely summarized. The general plans for dealing with substandard lives are also described, and illustrated by explanatory charts.

The methods of meeting additional risks are fully explained—the extra premium method, the lien method, the rated-up method, and the special classes method (the latter consisting of three groups of extra mortality averaging 38 per cent., 63 per cent., and 88 per cent. above normal). It appears that the lien method is passing out of favour in America. Possibly it does not appeal to the psychology of the American, or it may be that the elasticity of the method is not sufficiently appreciated. It should be remembered that a suitably adjusted lien, constant or decreasing, will meet practically any type of extra mortality; it is perhaps not generally recognized that a constant, or even a slowly decreasing, lien will cover an increasing extra mortality. The "numerical" method of assessment is also explained; it appears to be used in America more particularly for assessing extra risk in connexion with such factors as height, weight, build, family history, and occupation, taken in relation to the class of policy. But the expounder of the plan refers to its comparatively recent origin, and does not seem too optimistic about its intrinsic value, although it is admitted that experience may justify its more general adoption. The volume also contains interesting chapters on health, accident, and disability insurance. There are, moreover, some illuminating remarks on health conservation and insurance welfare work; but although the aims are undoubtedly admirable, the schemes are of too recent development to permit their results to be gauged.

<sup>2</sup> *Life Insurance Examination*. Edited by Frank W. Foxworth, Ph.D., M.D., Indianapolis, Indiana: London: Hery Kimpton, 1924. (Med. Bro, pp. 728; 156 figures. 45s. net.)

The chapters on blood pressure and urinary analysis are excellent, but such subjects as the classification and descriptions of malignant neoplasms are unnecessary in a work of this description.

The final chapter, on "Postponement in disease," is particularly interesting and exhaustive. The joint experience of the leading insurance medical specialists of America, tabulating their opinions as to acceptance, postponement, or declension in connexion with some 300 diseases, is worthy of examination by British medical officers and actuaries. The printing and the illustrations are excellent.

### A FRENCH TEXTBOOK OF THERAPEUTICS.

When a volume on clinical therapeutics has reached its eleventh edition, and has besides been widely read in translation, comment on its merits is surely superfluous. The new edition<sup>3</sup> of Dr. Lyon's treatise is a worthy successor to its forerunners, and will no doubt achieve as wide a popularity. In the preparation of a new edition the problem of judicious elimination to make room for new material is seldom easy, but Dr. Lyon has solved it. The whole edition has been entirely recast. The elimination has been effected at the expense of novelty, of many passages devoted to certain etiological aspects of disease, and of descriptions of treatment now no longer recommended. There are many noteworthy additions. There is a succinct presentation of the subject of the cardiac arrhythmias, and a very full description of their treatment by means of quinidine. The recent researches throwing new light on the functioning of the sympathetic nervous system have rendered necessary the inclusion of a special chapter under this heading. The chapter on hysteria has been revised, and the teachings of Babinski followed in the main. There is a special chapter on protein shock and protein shock therapy. The treatment of syphilis by bismuth and of gonococcal infections by vaccines is fully described. The insulin treatment of diabetes, including recent modifications in its mode of employment, is fully dealt with. In his last (tenth) edition the author drew the attention of his readers to the modern orientation of therapeutics, which tended more and more towards the employment of vaccines, of serums, and of glandular extracts. He now declares this tendency to be even more marked, and refers to the employment of protein shock therapy and of autotoxotherapy as evidence of how increasingly the trend is towards therapy of a biological nature. The practitioner, of course, may not be in a position to carry out treatment which involves a complicated technique, but he must at any rate, Dr. Lyon says, be prepared to take samples of blood, of sputum, or of exudates for examination, or to perform lumbar puncture. Detailed instructions are given as to how such samples should be collected. He must also be prepared to carry out certain modes of treatment—the intravenous injection of arsenobenzol and of organic serums, to inject antidiptbthelial serum, to perform transfusion, and to induce an artificial pneumothorax. Dr. Lyon's instructions under these headings are conspicuously practical and complete.

The present edition has suffered in no wise from the eliminations, and has gained notably by the additions above referred to. We do not doubt that it will receive as ready a welcome as its predecessors, and so retain its well merited popularity.

### DE SCHWEINITZ'S "DISEASES OF THE EYE."

A book which has reached its tenth edition is obviously a good one, and Dr. Schweinitz's *Diseases of the Eye*,<sup>4</sup> the first edition of which dates from 1892, hardly needs any words of ours to recommend it.

As an introduction to the study of ophthalmology, more especially for the senior student, it is unsurpassed, and it

<sup>3</sup> *Traité Élémentaire de Clinique Thérapeutique*. Par le Dr. Gaston Lyon. Onzième édition. Paris: Masson et Cie. 1924. (Sup. roy. Bro, pp. xiv + 1408. Paper cover, fr. 70; cloth, fr. 85.)  
<sup>4</sup> *Diseases of the Eye*. By George E. de Schweinitz, M.D., LL.D., Univ. of Penna., Sc.D., Univ. of Mich. Tenth edition, reset. Philadelphia and London: W. B. Saunders Company. 1924. (Roy. Bro, pp. 855; 7 plates, 434 figures. 50s. net.)

is worthy to rank with the well known translation of Fuchs's great work. The word "introduction" calls to mind the remark of the schoolboy who opined that Caesar's *Commentaries* were written as an introduction for those beginning the study of the Latin tongue.

Recent advances in ophthalmology have necessitated a good deal of revision of the text; the slit-lamp work is new since the appearance of the last edition in 1921; the new illustrations number twenty-five; some of the old pictures have been redrawn. The very complete index adds materially to the value of a book which can confidently be recommended as one of the best in our language on its subject. It is a costly book and will hardly be within the means of junior students; but the man beginning the study of eye diseases in order to specialize in that branch will find it a good and safe guide.

### CHRONAXY.

DR. GEORGES BOURGIGNON describes his treatise on the chronaxy of man<sup>5</sup> as a study of the general physiology, normal and pathological, of the neuro-muscular and sensory systems. It is a large work dealing with a subject the importance of which, both for electro-physiology and for electro-diagnosis, has recently been recognized. Although the term "chronaxy" dates from 1906, most of the experimental work on which this volume is based has been done since 1915 by the author, who is director of the electro-radiotherapeutic department at the Salpêtrière.

The essence of the investigation is the recognition of the time factor as entering into the conception of the excitation of muscles and nerves. As long ago as 1848 Du Bois Raymond, working with the frog's gastrocnemius and the constant current, announced that the excitation (stimulus) depends only upon variations in current density and not at all upon the time of the passage of the current. Hoorweg (1892-97), using condensers for stimulation, introduced the consideration of the "liminal voltage" or voltage necessary to elicit the liminal contraction, and, having regard also to the "capacity" and the quantity of electricity, he related these variables in an equation (law of Hoorweg). In 1901 Georges Weiss introduced the consideration of the time factor in a statement which related the liminal intensity and the time during which the current was passing. M. and Mme Lapieque completed these researches by their definitions of "rheobase" and "chronaxic" (1906-23). By rheobase they mean the current intensity necessary to elicit the threshold (*seuil*) of contraction on closing the constant current, and by chronaxy they mean the time of the passage of the current (necessary to elicit the threshold contraction) when its intensity is twice that of the rheobase.

Dr. Bourguignon has investigated the problem involved in the experimental aspect of this comparatively new subject; he has dealt with bipolar *versus* unipolar methods, the distribution of the current between the poles on the skin, "virtual" poles, the resistance of the living tissues, and the reduction of potential from the source of stimulation.

Dr. Bourguignon has gone over the whole subject of the regional distribution of motor and sensory points. He has determined the chronaxy of every accessible muscle in the body, and has brought out some facts that could not have been foretold. Some of these are that all muscles engaged in a particular function—for example, flexion—have the same chronaxy, and that all their synergists have the same chronaxy, whereas all the antagonists (extensors) have a chronaxy just twice as great. These relationships extend even to the muscles of respiration, for the muscles of expiration have a chronaxy double that of those of inspiration. In a limb the distal muscles involved in any action have a greater chronaxy than the more central. If  $\sigma$  stands for 0.001", the actual value of the chronaxy of the flexors of the forearm is from 0.08  $\sigma$  to 0.16  $\sigma$ , and for the extensors from 0.2  $\sigma$  to 0.36  $\sigma$ . The chronaxies of the sensory nerves have been ascertained by stimulating the nerves through the skin and noting the moment of perception of the peripherally referred sensations

of formation (method of Duchenne). In any given nerve or posterior root, fibres with different chronaxies are intermingled. The map of the distribution of sensory fibres possessing the same chronaxy is regional, and in any given region the chronaxy of the nerves is the same as that of the subjacent muscles.

Dr. Bourguignon has even attempted to estimate the chronaxy of the optic nerve by observing the production of the phosphene. It varies from 1.24  $\sigma$  to 2.36  $\sigma$ .

A large part of the book is occupied with the determinations of the chronaxies of muscles and nerves in various pathological conditions. While the chronaxy is normal in such states as athetosis, myoclonus, choreiform movements and tremor, it is greater than normal in states of contraction. An interesting fact has been brought to light in regard to the chronaxy of synergists in certain abnormal states—namely, that it is not of the same value as that of the muscles in whose function the synergists co-operate.

The comparative physiology of the chronaxy of muscle has also been studied, and has been determined in the frog, toad, snail, heart of tortoise, and stomach of frog.

There is no index, but in its place a detailed and well arranged table of contents.

### A GERMAN TEXTBOOK OF OPERATIVE SURGERY.

A TEXTBOOK in English will almost certainly always be preferred by the English student to any foreign work. The preference is wise, for it is desirable that the student should be careful to base his knowledge on the doctrines and methods of the practical workers and teachers of his own country. There are occasions when the rule may be relaxed in favour of certain textbooks written and published in the United States, and such a work as Osler's *Medicine* makes an equal appeal on both sides of the Atlantic. Many of the smaller French textbooks are excellent, but they are best read by the senior student who has knowledge enough to appreciate the differences in methods and opinions and wishes to widen his horizon. Not so much can be said for the majority of German textbooks. There are exceptions, but usually their authors seem to have failed to make themselves acquainted with things done beyond the German frontier, or written in any language other than German. Consequently their textbooks cannot be recommended either from the educational or examination point of view to English students, even those who read German fluently.

If an exception is to be made it must be because the book possesses some special qualities. Such an exception seems justified in the case of the late Professor ZUCKERKANDL's book on operative surgery, the sixth edition<sup>6</sup> of which has recently been prepared by Professor SEIFERT. The book is intrinsically good, and surgery is so much of an art that it is useful for the senior student and young surgeon to learn how things are done in other countries.

Professor Seifert asserts that it is the oldest of the textbooks on the subject now in use, and, while making the additions necessary to bring the book up to date, he has preserved the essential characters of the original work as far as possible. In particular, he has been careful not to go beyond its original scope—namely, the description of typical operations and operative procedures. Although the book is elementary in the sense that the simplest matters are explained, it is nevertheless comprehensive, extending from such simple procedures as the puncture of a hydrocele to resection of the pylorus, choledochoduodenostomy, and extirpation of the larynx. The subject is divided into general and special parts—the former dealing with the position of the patient during operation, the incision and division of tissues, the arrest of hæmorrhage, and the management of the operation wound; the latter dealing with the operations themselves, in the usual regional order of classification. Ophthalmic and gynaecological operations, however, are not included. The special qualities of the book are to be found in the diction and the illustrations. The descriptions are exceptionally clear and

<sup>5</sup> *La chronaxie chez l'homme: étude de physiologie générale (normale et pathologique) des systèmes neuro-musculaires et sensitifs.* Par le Dr. Georges Bourguignon. Paris: Masson et Cie. 1923. (Roy. 8vo, pp. iv + 417; 52 figures, 122 tables. Fr. 35 net.)

## Nota et Vetera.

### THE SERJEANT-SURGEONS TO THE KING.

THE death of Sir Frederick Treves in December, 1923, left Sir R. Harelock Charles the sole Serjeant-Surgeon to the King.

It is not known when this ancient and honourable office was first instituted, but it is probable that it existed long before the year 1461, when William Hobbes, Warden of the Barber Surgeons' Company, was appointed by Edward IV. As it was the duty of the serjeant-surgeon to accompany the sovereign on the battlefield, it is likely that Hobbes saw some service in those troublous times, but we know nothing of his career.

Nowadays the sovereign is well provided with medical attendants. There are in England seven physicians, five surgeons, four surgeon-apothecaries, three surgeon-oculists, a laryngologist, and two dentists, who form the personnel of the medical department of the Royal Household. In Scotland there is a physician, two surgeons, an oculist, two apothecaries, and a surgeon-dentist. In Ireland there are two physicians, two surgeons, and an oculist. But some of these offices are purely honorary.

Sergeanty or sergeancy is a form of tenure, and has been thus defined by an old writer: "Grand sergeancy is where a man holdeth his lands and tenements by doing some special service to the king in person." Thus the word "serjeant," as applied to lawyers and surgeons, implies personal service, and no doubt it meant in this case that the surgeon was a personal attendant on the king, but, despite any implications which some may think this to involve, the holder of this title ranked above the Regis Chirurgus Principalis, or chief surgeon, and to-day he comes directly after the physicians and before the surgeons in ordinary and other members of the medical department.

It must not be supposed that in Tudor times, because the serjeant-surgeon belonged to the Company of Barber Surgeons, he shared the monarch's chin or cut his hair. These duties were performed by the king's barber, who also belonged to the Company. In the later centuries of the existence of a fraternity of barbers its members had differentiated into two classes—those who practised what was called "barbery," including blood-letting, and those who practised only surgery, from which latter class the royal surgeons were chosen. Barbers only added surgery to their functions when the clergy were forbidden to practise it. As Mr. Austin Young says:

"Up till about the twelfth century the practice of surgery and medicine was . . . almost wholly confined to the clergy. . . . In 1163 the Council of Tours, under Pope Alexander III, considering that a practice which involved in its operations the shedding of blood was incompatible with the holy office of the clergy, forbade them to interfere in any matter of surgery; the consequence of this edict was that they gave over the operations of surgery, but continued to practise the healing art of medicine."

In London, however, there was a separate Guild of Surgeons, which was incorporated with the Barbers' Company by Act of Parliament in 1540.

At first there seems to have been only one serjeant-surgeon at a time, but from 1560 to 1891 there were two, and occasionally a third or extraordinary one was appointed who received no pay. After the death of Sir Prescott Hewett in 1891 the office was again single for a few years until the late Sir Frederick Treves was appointed in addition to Lord Lister, who had succeeded Sir James Paget. Treves was at first honorary serjeant-surgeon, and Sir Thomas Smith was made honorary serjeant-surgeon in 1901.

In Mr. Austin Young's sumptuous work *The Annals of the Barber-Surgeons of London* there is a list of such members of the Company as have served the office of serjeant-surgeon, and since practically all the serjeant-surgeons before 1745 belonged to the Company this list, which carries us down to 1736, is fairly comprehensive. A more complete list was published by Mr. (now Sir) D'Arcy Power in this JOURNAL (vol. i, 1900, p. 583). Some of the entries are to us but shadows of names, but others are records of men distinguished in their art, such as Thomas Vicary, of whom, however, a detractor wrote that he was "at first a meane practiser in Maidstone untill the King advanced him for curing his sore legge." It is to him that

Henry VIII is lauding (without looking at him) the charter of the Company in the great picture attributed to Holbein now hanging in Barbers' Hall. Like so many other well known surgeons of the sixteenth and seventeenth centuries, Vicary was on the staff of St. Bartholomew's, which was the only hospital—in the modern sense of the word—in the city of London. He continued to be serjeant-surgeon to Edward VI, Mary, and Elizabeth, and was surgeon to King Philip. Of Ferris we know little, save that Henry VIII left him 100 marks in his will, and that his own will is extant with a bequest to his daughter Thomazine of his "Courte bedd and bedstede and half a garnish of pewter vessels." His successor, Robert Balthrop, is only remarkable for his epitaph in the Church of St. Bartholomew the Less.

"Here Robert Balthrop lies intombed, to Elizabeth our Queene  
Who Sergeant of the Surgeons sworne wore thirty yeeres but  
here."

He died at sixty-nine of yeeres December's ninth the daye  
The yeare of Grace eight hundred thirde deductyng nine a waye  
Let here his rotten bones repose till angells trumpet sounde  
To warne the monde of present chaunge and raise the dead  
from grunde."

The quaint but cumbersome conceit in which the date of 1591 is recorded, and the erroneous description "Sergeant of the Surgeons," are perhaps due to the difficulties encountered by the writer in versification. Balthrop's Will also is interesting in that it contains a list of books and surgical instruments, including a salivatory. He left "one of my Launceetts that is sett in golde and enameled, to my felow Goodorus." This was William Gooderus, who was Master of the Company in 1594 and serjeant-surgeon.

William Clowes the younger was serjeant-surgeon to Charles I. His better known father, whose books "are the best surgical writings of the Elizabethan age" according to the late Sir Norman Moore, was surgeon to Queen Elizabeth, but not serjeant-surgeon. The family to which these surgeons belonged was a gentle one "bearing tokens and arms of honour, helm, mantle, and crest," and Clowes was one of the first men of family to take up surgery as a profession.

Of Wiseman, who accompanied Charles II in many of his wanderings before the Restoration, Sir D'Arcy Power says that he was the first to rescue surgery in London from its subordination to the Royal College of Physicians. His works show him to have been a clinical observer of great acumen and a skilful practitioner. "He believed in the miracles wrought by the blood of Charles I, yet he married the granddaughter of a regicide."

King George II was the last of our kings who went into actual battle. His serjeant-surgeon, John Rauby, as in duty bound, accompanied him at Dettingen. The tradition of personal service in the field seems to have been broken through in the last war, for when his present Majesty crossed over to France he was not, we believe, accompanied by either of his serjeant-surgeons. The last Master of the Barber Surgeons Company who held the office of serjeant-surgeon was Sir Caesar Hawkins, who was Master in 1736 and was appointed serjeant-surgeon in 1747, two years after the separation of the surgeons from the barbers. He was the first surgeon to be made a baronet. His son, his brother, his nephew, and his grandson were all serjeant-surgeons. As his brother Pennell Hawkins was appointed before 1783, the two brothers must have held office together. Five members of this family held this office, the last of them, Sir Caesar Henry Hawkins, dying in 1884. When the first Sir Caesar's brother Pennell died in 1793, King George III appointed David Dundas to the vacant place. Dundas was an apothecary (or general practitioner) at Richmond, and as such (by by-law) ineligible to the high offices in the Company of Surgeons, to which the . . . had a traditional right. He protested to keep him out, and a legal contest seemed imminent, but he did not press his claim, and contented himself with the royal favour and a knighthood.

The great Sir Astley Cooper became serjeant-surgeon in 1828. Since his time Brodie, Lawrence, Fergusson, Paget, Hewett, Lister, and Treves have adorned the office and rendered it one of the most honourable open to the medical profession. The present occupant of the office is the only member of the Indian Medical Service who has held it.

## THE MEDICAL RESEARCH COUNCIL.

The Medical Research Council, as we recently had occasion to recall, owed its origin to the "research penny" which, in accordance with a provision of the Insurance Act, Parliament undertook annually to provide. After five years' experience of its working the enlarged scope already given to it was confirmed by a charter of incorporation, and it was given its present position under the direction of a Ministerial Committee of the Privy Council, to which the Medical Research Council makes an annual report. It was the tenth of these reports which was noticed in two recent issues.<sup>1</sup> In its report for 1919 the work done in the years 1914-19 was reviewed; in the new report is a review of the following five years 1920-24.

Development was very greatly affected by the war, which broke out shortly after the work was begun. The effect was both temporary and permanent. At the urgent request of the War Office, and with the whole-hearted approval of the nation, attention was at once turned to war problems. Some of them were peculiar to war conditions, but the majority were not, though their solution was made more urgent by war. As an example, the nature and treatment of shock may be taken. Shock was being produced with terrible frequency among the wounded, but it is a condition with which surgeons in peace have commonly to contend, and by which their best efforts in the treatment of patients after accidents and after operations are often defeated. It is significant that a most important contribution to this problem, probably the most important, was made by the late Sir William Bayliss, whose life had been devoted, not to surgery or medicine, but to general physiology. The success which attended the application of the principles and methods of scientific medicine to the medical war problems with which the public mind was then full had a very great, and as many were fain to believe a lasting, effect. One reason for being thus sanguine was that the public appreciation of the absolute necessity, if the war was to be won, of applying scientific methods to the production of engines of war and to counteracting the mechanical and technical devices of the enemy, was not altogether a new thing. An appreciation of the importance of science to industry had been growing steadily, though very slowly, in Great Britain before the war. The extraordinary development in Germany of certain industries immediately dependent on scientific research, and in particular that of dyestuffs, had greatly disturbed the complacency of British manufacturers. The fact that the demand for explosives was a call on that industry was, in a sense, fortunate. The public mind had also come to believe that it was already receiving great benefits from the application of scientific research to the prevention of disease and the preservation of health; it heard much of the extension of the principles of bacteriology and chemistry to these matters during the war, and the successful results came very nearly home to those who had relatives in the armies—and who had not? But though there was therefore reason to hope that the lessons taught would not be forgotten when the war organization for medical research was dissolved, there could be no certainty.

In the quinquennial survey published in 1919 it was said that on the whole most of the men best fitted for original inquiry were given the opportunity for it and were given pay from public funds. When the war organization was broken up many men marked by distinguished scientific achievement in the war were in danger of returning either to non-scientific work or to teaching posts so poorly paid that it would have been necessary for them to augment their stipends by doing professional work of a kind incompatible with serious further effort in research. If this was to be avoided it could only be by public subvention or private munificence; fortunately both proved available. The House of Commons, encouraged by the growth of public opinion, made further provision for the universities (now administered through the University Grants Committee); it increased the annual vote for the Medical Research Council, and made other votes for scientific, industrial, and agricultural research. The action of Parliament and the growth of opinion to which we have referred had two other effects: it stimulated the pious benefactor to give or leave money to supply the needs of scientific research, and notably those of medical research, and it made the lay authorities of many hospitals "newly alive to their responsibilities for aiding the advancement of knowledge, by which alone the work of mercy can be made effective." By fresh efforts they have acquired better support for the research departments, and money has been obtained from particular benefactors and from the general public by wide appeals for aid to investigations into particular forms of disease.

Differences of opinion have existed as to the relative values of attending to "specific medical problems" and to "supporting the advance of the general level of the sciences contributory to medicine." There is room for both, and the decision made in any particular case must depend upon its attendant circumstances. "In practice, however, it is found that to serve one of these objects is almost invariably to serve the other." There is a stage in the affairs of any science which, taken at the flood, leads to practical application. That stage had, by a happy coincidence, been reached in physiology when the war broke out. "The pressing need for bringing the best physiological knowledge to the aid of sailors, soldiers, and workers in their exposure to every kind of violence, hardship, and physical stress, brought the physiologists increasingly to their proper place within the field of preventive and curative medicine. . . . Fruit in practical usefulness is now being gathered from the long years of work which physicians were apt in the past to label as academic." Instances will occur to everyone; those mentioned in the report are the growing knowledge of hormones, which has given us adrenalin, pituitrin, and insulin; the studies of muscle function, almost notorious for its supposed uselessness to the practitioner, which have provided basic knowledge that now underlies many parts of the science and art of medicine and is removing empiricism from practical studies of the heart, of some nervous disorders, of physical training, and of industrial labour.

Faith must be put unreservedly in the scientific workers themselves; the best and earliest success can only come from their free and disinterested work in the pursuit of clues that may lie here and there. "Recent history shows that sterility is soon reached when scientific work is tied to particular practical issues and ceases to be a free search for knowledge as such." The university clinics set up on the unit system with the aid of the University Grants Committee are serving as the bridge, and the student of

<sup>1</sup> January 10th, p. 87; January 17th, p. 123.

to-day is learning a new spirit as he accompanies his teachers backwards and forwards across it. Most of the work which has made the real difference to the daily tasks of preventive and curative medicine in the last few years has come from the laboratories of physiology and biochemistry rather than from those of bacteriology and pathology, and, the report continues, "it is notable that the chief contributions coming from the new clinics have, as it happens, been in clinical studies of the functions of the heart, the regulation of the respiratory mechanisms of the body, and the excretory efficiency of the body, carried out by men trained to use the precise methods of physiology or biochemistry." If we are in any risk of exaggerating the importance of the laboratory we have the example of the great man whose death we have this week so deeply to deplore. The story of his life has proved that the same man may be both physiologist and clinical physician, bringing to his clinical problems all the refinements of the most recent physiological methods, and making them so plain, and so greatly simplifying their application, that the practitioner may be content to use the end-results at the bedside without himself going through the physiological mill Mackenzie so courageously entered.

The Medical Research Council has from the first acted in co-operation with the universities and the medical schools attached to the universities. Of the total resources of the Council at least £80,000 is expended annually at the universities in grants and other forms of assistance to selected workers. Such a worker may also receive pay from the university in respect of his teaching duties, but whether he does so or not the intellectual life and efficiency of the universities gain from the improved opportunities made for members of their staffs or from the addition of new workers in the research field. This policy has been consistently followed. The example of the Rockefeller Institute of New York in establishing a research hospital has not been imitated, because it was felt to have the grave disadvantages of extravagant cost and of wasteful divorce from the current system of medical education; instead, the policy of assisting research work in the medical schools has been pursued. But there are also more general problems in physiology, pharmacology, biochemistry, and other departments, and for their investigation the National Institute for Medical Research, with field laboratories associated with it, has been established and maintained. To this purpose £48,500 was applied last year. The remarkable success of the policy followed from the first is plain to everyone, and is, we will venture to add, in large measure due to the foresight and good judgment shown by Sir Walter Fletcher, who left his physiological work in Cambridge to accept the arduous office of secretary of the Medical Research Committee, which, when it was appropriately placed under the constitutional control of a committee of the Privy Council, was given the name of the Medical Research Council.

### THE OPIUM CONFERENCES AT GENEVA.

The opium conferences at Geneva have resulted in what has been described as a deadlock. The first conference consists of representatives of those countries which have opium-producing territories; the second is to consider the drug evil generally. Full details of the session of January 24th are not yet available, but it is reported that all the contentious questions which have perplexed the two conferences for the past two months have been shelved by reference to a joint committee of

sixteen members. Further plenary sittings of the conferences are postponed while this joint committee and the other committees proceed with their deliberations. It is added that the question whether the second conference is competent to deal with the American proposals of restriction of output to medical and scientific purposes and the suppression of opium smoking will not be discussed by the joint committee. These proposals, which seem to have been the occasion for the deadlock, are, according to Lord Cecil, to be raised later if necessary.

It had been hoped that the reinforcement of the British delegation by a Cabinet Minister might lead to some accommodation between the American proposals and those of Great Britain and India; this was desirable from every point of view. But, owing perhaps to insufficient information beforehand, Lord Cecil confessed himself to be involved in problems of greater difficulty than he had ever previously encountered at any international meeting, and he was betrayed into quoting figures as to the relative consumption of opium in the United States and in India which, at a subsequent meeting, he found it necessary to withdraw. We have previously<sup>1</sup> called attention to the uncertainty as to the competence of these conferences to amend the Hague Convention of 1912, to the difficulty of separating the question of opium smoking from other modes of abuse of these drugs, and to the need for more authoritative and skilled representation on behalf of Great Britain. It would indeed be lamentable if the agreement achieved at the Hague in 1912, 1913, and 1914, and the co-operation of nearly fifty Powers, already secured by the Dutch Government and the League of Nations, were now to be disturbed or further progress impeded by any sharp differences between the United States and this country. We sincerely trust that the joint committee of sixteen may find a way out of the present impasse. An initial mistake was probably made by the Assembly of the League in attempting to separate and refer to different conferences the question of opium smoking, its restriction or suppression, and that of the limitation of opium and coca products to medicinal and scientific purposes.

The whole problem has been greatly complicated by the enormous increase of opium cultivation in China after its practical extinction in 1917. The excess of the world's production of the drug has thereby been augmented, and smuggling in the Far East appears to be rampant. Unfounded assertions have been made to the effect that opium grown in India is responsible for drug addiction in America, but no one acquainted with the facts would need to be reassured by the emphatic repudiation of this assertion by Lord Olivier, the late Secretary of State for India, which appeared in the *Times* of January 16th.

It will be remembered that by Articles 6 and 7 of the International Opium Convention of 1912 it was enacted that "The Contracting Powers shall take measures for the gradual and effective suppression of the manufacture of, internal trade in, and use of prepared (i.e. smoking) opium, with due regard to the varying circumstances of each country concerned, unless regulations on the subject are already in existence"; and "The Contracting Powers shall prohibit the import and export of prepared opium; those Powers, however, which are not yet ready to prohibit immediately the export of prepared opium shall prohibit it as soon as possible." That was eleven years ago, and the American proposal that such imports shall

<sup>1</sup> BRITISH MEDICAL JOURNAL, December 6th, 1924, p. 1071, and January 10th, 1925, p. 83.

be reduced by 10 per cent. annually for ten years would not seem to be unduly expeditious. The counter-proposal put forward by the British Government is that opium smoking shall be abolished in British Far Eastern territories within fifteen years from such suppression of opium production in China as will preclude the drug being smuggled into those territories. This suggestion was stigmatized by Dr. Sze, the Chinese delegate, as "an attempt to escape from a definite obligation by subordinating it to a condition depending on the internal situation of another country," and Mr. Porter, the American delegate, could not admit that "any justification existed for even a temporary suspension of an obligation which rested upon every nation signatory to the Hague Convention."

In a recent paper read before the Royal Society of Tropical Medicine, Professor W. E. Dixon contended, in regard to smoking opium, that "this way of taking opium is by far the least objectionable, because the amount of alkaloid taken is so small." This view appears to conflict with what may be termed the official or administrative view in India, and if correct would seem to indicate that administration by way of ingestion or injection requires to be more seriously regarded and more effectively restricted than the smoking of opium. An interesting article in the *Times* of January 26th gives alarming figures of the extent of drug addiction, especially of heroin and cocaine, in the United States, and the enormous sums—estimated at over £40,000,000 a year—spent by these wretched addicts in procuring their supplies. It concludes by stating that the one certain "way of cutting off supplies is to limit the production of opium and of coca leaves in their countries of origin."

#### THE RIVERS MEMORIAL MEDAL.

THE council of the Royal Anthropological Institute recently determined to commemorate W. H. R. Rivers, M.D., F.R.S., who was its president at the time of his death, by founding a Rivers Medal, to be given annually for meritorious anthropological work done in the field. The first presentation of the medal took place at a meeting of the institute on January 27th, when the award was made to Dr. Alfred C. Haddon, F.R.S., reader in ethnology in the University of Cambridge, in recognition of his work in New Guinea, Torres Strait, and Borneo. The president of the institute, Professor C. G. Seligman, in presenting the medal (which has been struck by the Royal Mint and bears a bust of Dr. Rivers on the obverse), said that the names of W. H. R. Rivers and Alfred Cort Haddon were closely united in many ways. In honouring both on this occasion anthropologists were praising famous men and—for he might well carry the quotation further—"our fathers that begat us." There was no one who had added anything to the science of anthropology during the last fifteen years who was not indebted to a greater or less extent to one or other or both of these men. They worked together, and personally he had no doubt that neither of them would have achieved what he did had he worked alone. The medallist of that evening, upon whom this honour was most naturally and fittingly bestowed, was the first man to organize a really important anthropological expedition in the field. Every working anthropologist, directly or indirectly, was under obligation to the initiative behind that expedition to the Torres Strait a quarter of a century ago. The expedition proved to be the most important that had ever been organized, and it was a striking proof of Haddon's foresight that he determined that it should be not only an anthropological but a psychological expedition also,

and that half of its members should be trained psychologists. The opportunity of that expedition sent the subtle spirit of Rivers roving over that fascinating "no man's land" in which ethnology, psychology, genetics, sociology, and even medicine all interpenetrated. There he experimented to some extent, but more than anything else he speculated, and speculated brilliantly. Professor Seligman added that he had had the privilege of working with Rivers in the field, and he was able to see the very distinct connexion between the genealogical method which he hammered out in Torres Strait and the work he did for shell-shocked soldiers in the war. After speaking of the work of Dr. Haddon as author and teacher, he said it was with mingled respect and affection and sorrow and pride that he presented the Rivers medal for the first time. Dr. Haddon, in acknowledgement, said that he was very happy to have his name associated with that of his old friend and colleague. After his own first expedition of 1889 he gained an appreciation of the fact that psychology was an integral part of anthropology, and he determined that if he had opportunity in this direction he would not neglect it. When he was preparing for the Torres Strait expedition in 1893 he asked Rivers to join him, and Rivers refused, but later, finding that C. S. Myers and another of his best students were going, he changed his mind and asked to be allowed to join the party. The consequence was that for the first time natives were studied psychologically in their own country by trained psychologists with adequate apparatus.

#### SEX RATIO AND ITS CONTROL.

THE sex ratio is the relative numerical proportion of the sexes within the group. There must be a sex ratio at all times after sex is determined, but it is convenient to take conception, birth, and maturity as the three salient stages at which to consider the matter. These points are known as the primary, secondary, and tertiary sex ratios respectively. That usually considered is the secondary, which is measured by taking the number of males to a hundred females born. The primary is a demonstration of the sex-determining mechanism in operation, while the tertiary will provide an estimate of the post-natal survival of the two sexes. That this subject is of more than academic interest is demonstrated by Dr. F. A. E. Crew in a recent paper.<sup>1</sup> To the dairy or egg farmer it is of supreme importance that females should preponderate in his young stock, and the question is not without its human interest. It seems probable that sex is determined at the moment of fertilization. It has been shown that there exists a mechanism tending to preserve in each generation the ratio of 1 to 1, and that this mechanism is inherent in the gametes in virtue of the production in equal numbers by one sex (the female in birds, the male in amphibians and mammals) of male and female reproducing cells respectively. Thus in mammals the female is homogametic—that is, produces ova capable of becoming either male or female; while the male is heterogametic—that is, produces sperms which are either male or female, but which, once produced, must determine the sex of the resulting embryo. The sex ratio is theoretically 1 to 1, but in practice this is never the case. Dr. Crew gives some interesting figures. In man the ratio is 103 or 107 to 100; in horses and sheep the males are in the minority; while in dogs, pigs, and cattle there are from 118 to 107 males to every 100 females. In certain animals it has been found possible, by careful in-breeding, to produce a line in which either males or females predominate. There is evidence that in man the sex ratio is low for births resulting from conceptions at the seasons of greatest fecundity and high at the times of lowest birth rate. This difference is possibly related to the relative physiological condition of the parents at the time. Statistical evidence

<sup>1</sup> *Inter. Rev. of Sci. and Prac. of Agric.*, Rome, II, 1924, pp. 554-570.

sometimes supports, sometimes contradicts, the belief that the ratio is affected by the relative ages of the parents. The old notion that one ovary produces only male eggs and the other female, and that they function alternately, cannot be brought into harmony with established facts, and is not accepted by geneticists on present-day evidence. Unilateral ovariectomy does not result in the production of young of only one sex—in fact, the evidence all tends to show that in mammals the sperm always carries the sex-determining constituent. Experimentally, the sex ratio can be varied, but in nature the deviation from the theoretical number is probably most often due to a differential activity, susceptibility, or mortality on the part of the two kinds of sperm. An individual with the chromosome constitution of one sex (a determined male or female) may come to possess the functional sex equipment of the opposite. A hen, for example, may function as a cock, and when mated with a hen will provide offspring with a ratio of 1 to 2; whereas a female mammal functioning as a male will produce progeny exclusively female. The problem of the control of the sex ratio is that of the control of the differential production of the gametes by the heterogametic sex, of the control of the physical and physiological dimorphism of these, or of the production of complete sex reversal.

#### "RADIO" DIAGNOSIS.

THE exploitation of wireless as a means of medical charlatanism appears to be now in full swing in the United States. It is like the outburst of electric quacks that followed the discovery of magnetism and electricity. We are not surprised to learn, therefore, from the *Radio News* that a new method of "radio" diagnosis has been evolved: this is the neurophonometer of one G. D. Rogers, D.C., Ph.C., a chiropractor from Texas. Since these new American contraptions have a way of crossing the Atlantic rapidly, medical practitioners in this country may find it convenient to be acquainted beforehand with the name of any new marvel that may be brought to their notice by credulous patients. The *Radio News* describes the neurophonometer as a regular radio receiving set, fitted with a headphone and two additional leads. One of these leads is attached to the forehead of the patient, while the other is applied to various sites on the patient's back. The operator wears the headphone, and tunes in the set until he hears a maximum sound. By this means he can ascertain in ten minutes the "capacity and inductance of the brain," and can determine which spinal nerves show a divergence from this inductance. Chiropraxis, as some of our readers may remember, teaches that all disease is due to compression or interference with spinal nerves, and this machine enables the chiropractor to know the nerve on which he should start operations. This all sounds delightfully simple, but the *Radio News* treats the thing in a spirit of mocking disbelief. Thus it heads its article "The latest radio swindle"; it writes of "the crass nonsense of the technical verbiage"; and it uses unkind expressions such as "hokum," "humbug," "pure bunk," and "fool the public." Our contemporary mentions that it has had occasion before to issue warnings against the crop of unscrupulous exploiters who have sprung up to take advantage of the public interest in wireless, and it compares them with burglars, to the advantage of the latter. It concludes by offering to pay Rogers 1,000 dollars if he can convince a scientific committee that his claims are true. The trouble about "inventions" of this kind is that they are so numerous and so varied. Most of them die a speedy death, but a few catch on, and it is just as hard to say which one will hold the public fancy as it is to say which pantomime song will captivate the hearts of the London errand-boys.

<sup>1</sup> *Radio News*, December, 1924, p. 514.

#### UROSCOPY.

At a meeting of the Section of the History of Medicine of the Royal Society of Medicine, held on January 21st at the Wellcome Historical Medical Museum, Professor Gask read, on behalf of Mr. Alban Doran (who could not be present), a short communication on bed-bottles and glasses for uroscopy. Mr. Alban Doran's exhibit consisted of three bed-bottles, one for male and two for female patients. They were recently purchased in a curiosity shop in Oporto, Portugal, by Lieut.-Colonel Croft Lyons. Made of white flint glass, they appeared to be uroscopy glasses for the examination of urine, such as are figured in the works of Johannes de Ketham (a set from Leipzig University, 1400) and Fletcher (1641), and in the pictures of Gerard Dow and van den Bosch, painted in the seventeenth century, copies of which were exhibited. On close examination, however, and comparison with samples of both kinds of glasses in the Wellcome Museum, it became clear that these three bottles were made for the use of invalids in the recumbent position, and not for the preservation of urine for examination. They were known to English nurses as "bed-bottles," and were much in use down to the end of the eighteenth century in this country, and remained popular in Southern Europe until later times. The curator of the museum (Mr. C. J. S. Thompson) then showed and described a number of specimens of uroscopic glasses, dating from the fifteenth to the seventeenth centuries, now under his care. The antiquity and purpose of such glasses were discussed by Dr. J. D. Rolleston, President of the Section, Dr. Parkes Weber, and others. In mediæval art the physician is, in a very large proportion of cases, depicted in the act of inspecting urine in a glass. As Garrison says: "Uroscopy or water-casting was, in fact, a favourite theme of the painter and wood-engraver down to the beginning of the eighteenth century, and the accessories in these representations are nearly always the same. The urinal became the emblem of medical practice in the Middle Ages." We seem to remember that one of the Florentine churches is decorated with a carving in stone, by Giotto, showing a physician in the conventional attitude examining a specimen of urine, and attended by persons carrying the usual urine basket. The meeting concluded with a very interesting display of anatomical manikins exhibited by Mr. Thompson. The bed-bottles shown by Mr. Doran are preserved in the museum of the Royal College of Surgeons of England.

#### THE SCIENTIFIC OUTLOOK IN VENEREAL DISEASES.

IN his address from the chair of the Medical Society for the Study of Venereal Diseases, on January 23rd, Colonel L. W. Harrison said that many clinicians worked too much on empirical lines, content to follow a path recommended by some enterprising author without any clear idea of the principles which should govern their line of action. A new situation, created, for example, by some abnormal or anomalous symptom, drove them to a book, not to discover the underlying pathological processes, but to find out what the author did in a like situation. Often also clinicians and pathologists worked in water-tight compartments. Much of the criticism levelled at the reliability of the serum tests for syphilis sprang from a lack of knowledge on the part of many clinicians of the scientific principles and technique of the tests, and a consequent inability to understand the pathologist's point of view. For example, a reaction was often—too often, he thought—described by the pathologist as "weakly positive." A clinician who had not taken the trouble to understand the test, on receiving this report, and having a suspicion already that the patient was suffering from syphilis, might seize upon the word "positive" and use it as his justification for a diagnosis,

thereby inflicting not infrequently on a non-syphilitic patient a great amount of mental suffering. A little knowledge of the technique and a little conversation with the pathologist would prevent the clinician from accepting the report of a "weakly positive" reaction as justifying anything more than a suspicion, and would make it clear to him that between the plainly syphilitic reaction and the plainly negative there was a zone into which some non-syphilitic serum now and then wandered. The pathologist, in reporting a serum as "weakly positive," never intended to convey more than a doubt, and was not in the least surprised to find the same serum a week later giving a negative reaction. Colonel Harrison went on to remind the society of a few of the ways in which laboratory work had advanced the arts of diagnosis and treatment, and said that workers in venereal diseases owed more than those in most other branches of medicine to laboratory research. Arsenobenzol compounds were largely the product of pure research. The bismuth treatment owed its existence to a surmise by a chemist that from its chemical structure bismuth should be antispasmodic. The serum tests of syphilis were due to the laboratory, also the discovery of the micro-organisms of syphilis and gonorrhoea. Histologists had shown the toxic effects of antisyphilitic treatment, and biochemists had indicated some of the ways in which these toxic effects might be avoided. He spoke also of the value of a laboratory training to the clinician, and added that he felt keenly the debt which he himself owed to his training in laboratory methods of attacking problems. The laboratory worker had the advantage over the clinician that his observations could be more exact, he obtained his results much more quickly, and wrong processes of thinking were corrected sooner. The speaker illustrated his point from the attack made on the vaccine therapy of gonorrhoea; this attack had usually been based on the mere impression of an observer that cases treated with vaccines did no better than those treated without, but very often no attempt was made to discover exactly whether the cases treated with vaccines were under the same conditions as those not so treated, no exact computation was made of the results with regard to complications or the period of infectivity, and no thought was given to the possibility of the particular vaccine which was employed being an indifferent immunizer. The observer, in fact, generalized from his mere impression that vaccines were useless in the treatment of gonorrhoea. Certainly there would be every advantage in the closer study by the clinician of the scientific principles involved in the diagnosis and treatment of venereal diseases. The clinician who viewed clinical phenomena from the pathological standpoint developed ideas as to methods which might combat the pathological process. These ideas he took to the pathologist, and together they worked out a line of research which was more likely to be fruitful than if the clinician had simply, in some haphazard way, put his serums to the test. He pleaded that the clinician and the pathologist should each learn something of the other's work, and endeavour to understand its possibilities and limitations.

### "GLÜCKSGEFÜHL."

The *Glücksgefühl*, which is the subject of a monograph by Dr. Rümke of Amsterdam,<sup>1</sup> is difficult of definition. It is not the ordinary sensations of joy, pleasure, or happiness that are dependent on external excitation, nor is it the sense of physical well-being. It is essentially psychic, and arises unexpectedly and spontaneously from the innermost psyche of the individual who experiences it; it permeates his whole being, and colours all animate and inanimate objects within his horizon. It is, in fact, much of the same nature as that which Wordsworth describes in his "Tutima-

tions of Immortality": "The earth and every common sight" seems "apparelled in celestial light." This peculiar sensation of bliss is analysed by Dr. Rümke from manifestations of it amongst psychopathic and neurological patients, in the aura of epileptics, and in persons under the influence of such drugs as opium and cannabis-indica. His object is to give prominence to his method of analysing phenomena in psychic conditions. He has examined the medical histories of 5,000 cases in the Valerius Psychiatric and Neurological Clinic of Amsterdam. In only nine, however, did he find material suitable for his investigations. He dissects these cases in detail, recording first the phenomena in each case, and in later pages of the book the family and medical history of the patient. He also describes and analyses nine cases reported by other writers as occurring in conditions of neurasthenia, epilepsy, mental disease, and opium intoxication, contrasting them with the cases from the Valerius Clinic. The monograph chiefly consists of a meticulous examination of the manifestations of *Glücksgefühl* in all these cases and in all their aspects and bearings. A wide German and French literature comes within the scope of Dr. Rümke's investigations. It includes, for example, the metaphysical and sociological writings of Schopenhauer and Nietzsche. The only works in English referred to are McDougall's *Introduction to Social Psychology* and James's *Varieties of Religious Experience*. In his concluding remarks Dr. Rümke emphasizes the value and possible future development of a study of the phenomena from a prognostic point of view, but states that clinically, etiologically, and therapeutically his method leads to nothing; and, indeed, to use his own expression, might appear to be a process of "splitting hairs." But patients who have experienced *Glücksgefühl* may, when the phenomena present certain favourable characteristics, recover their sanity and remain sane for years, while those with unfavourable characteristics do not. It is in the differentiation between the favourable and unfavourable manifestations that Dr. Rümke believes his method of investigating phenomena is of value. When its limitations are recognized it becomes, therefore, an auxiliary to other clinical methods in psychiatry because of its value in prognosis.

### JOSEPH ROLLET.

On the occasion of the celebration of the centenary of Joseph Rollet, who was born on November 24th, 1824,<sup>1</sup> Dr. L. Bonnet, in a special issue of the *Lyon Médical* published on December 7th, 1924, recalls that Rollet had originally intended to devote himself to surgery, but that on his appointment as surgeon-major to the Antiquaille Hospital at Lyons he determined to concentrate his attention on venereal disease. The introduction to his book published in 1861, entitled *Recherches cliniques et expérimentales sur la syphilis, le chancre simple et la blennorrhagie*, is printed in the same number of the journal. In it Rollet pointed out that the historical method employed by Astruc and the experimental method of inoculation introduced by John Hunter are not the only guides in the investigation of venereal disease, but may be compared to roundabout paths for scaling a mountain inaccessible by a direct route. In the majority of cases, he maintains, there is nothing to take the place of the good old method of clinical observation, whether in general medicine or in the domain of venereal diseases. At the time of Rollet's appointment to the Antiquaille Hospital in 1855, almost as much confusion reigned in the nosology of venereal disease as in the subject of sore throat and continued fever before the time of Bretonneau.<sup>2</sup> Rollet's principal achievement is to have established once and for all the absolute independence of the three venereal

<sup>1</sup> Zur Phänomenologie und Klinik des Glücksgefühls. By Dr. H. C. Rümke. Berlin: Julius Springer. 1924. (Sup. roy. 8vo, pp. 128. 1.45 dols.)

<sup>1</sup> See BRITISH MEDICAL JOURNAL, November 22nd, 1924, p. 581.

<sup>2</sup> See BRITISH MEDICAL JOURNAL, November 1st, 1924, p. 524.

diseases. He showed that those cases in which an apparently soft chancre was followed by constitutional syphilis there was not a mysterious transformation of one virus into another, but an association of the two viruses. Rollet's next most important work was the demonstration of the contagious character of the lesions of secondary syphilis, for he held that it is by this means that the disease is commonly transmitted. He was thus able to recognize and describe several new varieties of chancre caused by these lesions, such as mammary chancre, buccal and cephalic chancre, and the chancre of vaccinal syphilis. Rollet's other contributions to our knowledge of venereal diseases consisted in his demonstration of the syphilitic nature of that form of sarcocelo known as fungus testis, his work on gonorrhoeal rheumatism, and the early and masked forms of urethral stricture.

## ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

(Continued from page 172.)

The Royal Commission resumed its sittings on January 26th, the Right Hon. H. P. MACMILLAN, K.C., presiding.

### *Allegations of Wrongful Detention.*

The case of Mr. H. W. Holman, who at the previous sitting had alleged that he had been wrongfully committed as a lunatic to a mental hospital, was further investigated. Mr. H. C. Dickens, K.C. (instructed by the Medical Defence Union), appeared on behalf of five medical men who had been mentioned in Mr. Holman's evidence, and the medical witnesses were cross-examined by Mr. W. Stewart, secretary of the National Society for Lunacy Reform.

The Chairman at the outset said that Mr. Holman had addressed a most improper letter to the Commissioners reflecting on a medical witness. A court of law would take serious notice of such communications. He added that the Commission only desired to know why it was thought proper in Mr. Holman's case to issue an urgency order instead of the more deliberate reception order, and also to learn something of the circumstances of the certification, Mr. Holman having alleged that his examination before certification was insufficient and careless.

Sir Maurice Craig said that he first saw Mr. Holman in January, 1915, in consultation with his own doctor. He was stated to have been for two years very excitable and talkative, and once to have tried to throw himself out of an hotel window. He had delusions also that he was liable to arrest as a spy. He wandered from one subject to another in conversation, his pupils did not react well to light, and his reflexes were unequal. Among other signs was something which to him indicated other tests the condition from which the patient was suffering. As to the reason for an urgency order, the patient was at that time at the house of a doctor (Dr. Dempster), and there was no power of restraint. Mr. Holman threatened to leave, and the likelihood was that had he done so he would have got into the hands of the police, as he was not then in a fit state to take care of himself. The witness had tried to avoid sending the patient to a mental hospital by getting him to sign an undertaking to carry out certain promises, but this was broken. He asked Dr. Percy Smith to see the patient, and that gentleman had a long interview with him alone. What he (Sir Maurice) saw and knew of the patient certainly justified his detention.

After Mr. Stewart's cross-examination of the witness had proceeded for some little time, the Chairman expressed regret that the opportunities which Mr. Stewart was enjoying in cross-examining the witness were being largely wasted by irrelevant issues, apart from the loss of valuable time to many people concerned.

Mr. C. R. Steel, a solicitor, spoke to visiting Mr. Holman while he was detained at Moorcroft and executing a codicil revoking his will. He did not think Mr. Holman was of unsound mind, but his opinion against that of the doctors.

Dr. W. H. B. Stoddart said that he first came in contact with Mr. Holman in 1916, and he produced the notes he made of his condition at the time, taken at the home of Dr. Dempster. The question was whether he was in a condition to go unaccompanied to his home at Brighton, as he intended doing, and the witness considered that he should not go anywhere without proper supervision and control. The urgency order was rendered necessary by the patient's determination to leave and the fact that there then existed no power to detain him. The witness was cross-examined as to his recently modified views in favour of Freudism, and he admitted somewhat different angle. But this did not change his opinions on the question whether a given patient was certifiable. He added that there were impressions derived from a long interview with a patient which could not be adequately represented on the form of a certificate. He denied that he certified because he was told to do so; no doctor would do that. He was asked for his opinion and gave it very firmly.

On the following day, January 27th, the case of Mr. Holman was further investigated.

Dr. Percy Smith, examined by Mr. Dickens, said that he saw Mr. Holman in December, 1916, and from information received from three doctors and his own examination of the patient he came to the conclusion that he was insane and unfit to remain in the doctor's house, where he then was. In cross-examination by Mr. Stewart, the witness said that he could not tell how many patients he certified during 1916, but the patients he saw and did not certify were far more numerous than those he certified. He would do anything in his power to avoid certification so long as it was safe. Before seeing the patient he had a long talk with Sir Maurice Craig. He did not warn the patient that anything he said might be used as material to justify his detention; to do so in many cases would be extremely detrimental.

Mr. Stewart at this point read a judgement of Lord Justice Coleridge in 1885, in which he spoke of "the slimy stuff on which people are sometimes incarcerated in lunatic asylums." The Chairman said that that was previous to the Act of 1890, in which certain reforms were embodied, and what the Commission was now considering was whether the existing code was sufficient. Matters before 1890 were based on a very different régime. Dr. Percy Smith remarked that he was medical superintendent at Bethlem when the Act of 1890 was passed, and well remembered that the Act trebled all the certificates and reports a medical superintendent had to make with regard to patients of the private class. Mr. Stewart maintained that the Act of 1890 was a consolidating Act, and, save in one particular, brought about no alteration in procedure.

Dr. Percy Smith, in answer to a further question, whether, in the light of what was now known about Mr. Holman's case, he wished to express any regret that he had certified the patient, said that he had no regret at all. The Chairman said that if Mr. Stewart proceeded along such a line of cross-examination he would feel called upon to read communications—very serious communications—which had been received from Mr. Holman subsequent to his evidence, including a telegram received that morning.

Dr. Porter Phillips, medical superintendent of Bethlem Hospital, described how he was asked by Sir Maurice Craig to see the patient, and found him in a restless, excited, and talkative condition. He had great difficulty in questioning him because of his garrulity. He noticed unequal pupils, exaggerated reflexes, and a very tremulous condition. He came to the conclusion that Mr. Holman was of unsound mind. Mr. Holman took a fancy to the witness, and expressed his willingness to go with him to a home he had described with a view to treatment; and after consultation with Dr. Dempster, in whose house he was, it was agreed that advantage should be taken of the opportunity afforded by the patient's willingness to be removed, and the witness himself drove him to Moorcroft and left him there. He strongly denied that there was anything in the nature of a "trap."

After further evidence the Chairman announced that the Commission had heard sufficient of the case of Mr. Holman, and there was no need to call Dr. R. H. Cole, who was present and ready to give evidence.

### *National Society for Lunacy Reform.*

Evidence was then taken from Mr. Montgomery Parker, chairman of the National Society for Lunacy Reform.

Mr. Parker submitted, on behalf of his society, that there should be an immediate provision of voluntary hostels for early treatment supported by subsidy from the State and controlled by the Minister of Health through local health authorities, with no association with the Board of Control or any other board or department of State control of lunacy administration. There should be early adaptation of hospital wards to deal with incipient mental cases or temporary cases arising from illnesses. There should also be adaptation of infirmary wards to permit of observation. On the legal side there should be the methods of certification and the issue of the limitation of all unnecessary distinctions between private and pauper patients; no special fees to be payable to permanent officers functioning prior to certification; provisions to secure that the judicial authority should in all matters act judicially and not in an administrative capacity; adequate representation of the patient at all stages, and some further definition of the terms "lunatic" and "of unsound mind." With regard to institutional treatment the society submitted that it was desirable to establish a new and more representative central authority, with definite powers of direction, acting through assistant district commissioners, who should be trained administrators and not medical men. It laid stress on the urgent necessity of applying generally improved methods of curative treatment and improving the general environment of patients, of limiting where possible the numbers permitted in any one institution, of increasing the medical and nursing staff to permit of proper treatment, and of strengthening existing visiting committees with such provisions as would ensure their functioning, of a statutory provision that all institutions should appoint a body of authorized visitors independent of lunacy administration and licensed as in the case of prison visitors, the introduction of the judicial authority within asylums as an additional safeguard to the patients and the right of independent medical access to patients. There should also, in the society's opinion, be some provision that the senior medical officer should not be charged with responsibility for administrative duties. Other points set out were that there should be no punishment under the guise of "curative treatment" that there should be further provision to ensure that the existing methods of discharge were freely utilized in practice, and that after discharge there should be extended opportunity for after-treatment.

## England and Wales.

### NOTTINGHAM GENERAL HOSPITAL.

Mr. W. G. PLAYER of Nottingham, a past-president of the Nottingham General Hospital, and at present vice-chairman of the Hospital Board and chairman of the Extension Committee, has promised a subscription of £50,000 towards the capital sum required for the extension of this institution. Mr. Player had previously given £10,000 to the War Memorial Extension Fund of the hospital, and also endowed five beds at the cost of £5,000. The present subscription follows the lines of a scheme devised by the National Council of Social Service, under which charities are exempt from income tax in respect of income applied to charitable purposes. It is possible, therefore, that Mr. Player's subscription will ultimately result in as much as £70,000 accruing to the hospital. Great advances have been made since 1920; the income of the hospital has considerably increased, the overdraft at the bank has been extinguished, and the new nurses' home, erected as a war memorial, was opened by the Prince of Wales in 1923. We gave an account of this building on August 25th, 1923 (p. 339). In consequence of Mr. Player's gift it may now be possible to provide for the completion of the Ropewalk Wing of the hospital, and also, it is hoped, for the erection subsequently of the much needed wing for accident cases. The new out-patients' department, now being built, will cost about £80,000, and will contain a large central hall for out-patients, consulting rooms, an operating theatre, forty beds for throat, nose, and ear patients, orthopaedic wards, and x-ray and massage departments. It will be connected with the main hospital building by a subway. The estimated annual cost for maintenance of the new department will be approximately £5,000. As soon as it has been completed it is intended to build a new wing of the hospital containing 120 beds, which will increase the cost of maintenance by £10,000. During 1924 the Nottingham General Hospital received from the Hospital Saturday Fund over £24,000. Since 1919 the Hospital Saturday Fund has increased its contributions by £16,000, and the annual subscriptions have increased by £6,000. The total maintenance cost has risen from £20,000 per annum, prior to the war, to approximately £50,000 for 1924. The 235 beds available in 1913 have increased to 350. Some 5,000 in-patients are admitted annually, and 27,000 out-patients receive treatment. Accident and emergency cases have increased during the past ten years by more than 100 per cent. The oldest portion of the hospital was erected in 1782, and contains 44 beds. The hospital, which serves an area containing a population of more than half a million, will no doubt be visited by many of our readers when the British Medical Association meets at Nottingham in 1926.

### PROMOTION OF MEDICAL STAFF AT LONDON MENTAL HOSPITALS.

In 1919 the London County Council agreed to the principle of granting study leave to members of the medical staff at the mental hospitals, and the Mental Hospitals Committee also at that time laid it down that in making appointments to positions in the medical service special consideration should be given to candidates holding degrees in psychological medicine. The committee is now recommending to the Council that the promotion of members of the medical staff, other than those who were in the service on July 8th, 1919, to positions higher than that of fifth assistant medical officer, should be conditional upon the officer promoted possessing a diploma or degree in psychological medicine or obtaining such a diploma or degree within a limit of time to be specified by the committee.

### COMBE PARK ORTHOPAEDIC HOSPITAL, BATH.

Descriptions of the Combe Park Children's Orthopaedic Hospital at Bath were given in our issues of May 24th and July 26th, 1924. At a recent meeting of the General Committee of the hospital representatives of the Wiltshire County Council and clinics attended to discuss a scheme whereby arrangements could be made for the treatment of the crippled children of Wiltshire. The Marquess of Bath

presided, and, as the result of discussion, it was agreed to recommend that a board of governors be formed, including representatives of the Wiltshire County Council and local clinics. Since this meeting was held Somersetshire has also decided to take part in the scheme, so that eventually there will be one central orthopaedic hospital for the whole of Bath, Somerset, and Wilts, with clinics for the after-care of those patients who have been treated at the central hospital. The increased accommodation thus necessitated is receiving attention.

### THE INTERNATIONAL HEALTH CONGRESS AT WEMBLEY.

We gave an account in our issue of June 7th, 1924 (p. 1013), of the first International Health Conference organized by the People's League of Health at Wembley last May. The Conference dealt with "the latest knowledge regarding the causes, treatment, and prevention of disease," and a full report has now been published. The text of the various papers read, and of the discussion, will enable those who were present to recall the valuable information that was so lucidly set before them. The subjects dealt with were: housing and house sanitation; food, air, light, and water; some overseas and other diseases; mental hygiene; industrial hygiene; and legislation desirable with regard to health matters. Sir Clifford Allbutt contributes a foreword in which he indicates the value of the work accomplished by the People's League of Health. With regard to the evils characteristic of our civilization, he suggests that it is satisfactory to learn from the Conference that our embarrassment arises less from the number of arrears to be made up than from the continual rise in our standards. The report is published by the People's League of Health, and is obtainable at its headquarters, 12, Stratford Place, W.1, price 7s. 6d.

The League has arranged a course of nine lectures on diet, to be given during the present term at the house of the Medical Society of London, 11, Chandos Street, Cavendish Square, W.1, at 6 p.m. on each day. The first was given on Wednesday last by Dr. Leonard Hill, F.R.S., on the nature and purpose of food; the second, by Lieut.-Colonel R. McCarrison, C.I.E., M.D., on the food of mankind treated historically and geographically, will be given on Wednesday, February 4th. On the three following Wednesdays, Professor R. H. A. Plimmer, D.Sc., will lecture on diseases caused by badly chosen diets.

## Scotland.

### EDINBURGH ALUMNI ASSOCIATION.

A MEETING was held in the McKean Hall, Edinburgh University, on January 23rd in connexion with the recently formed Edinburgh University Alumni Association. Sir Harold Stiles, president of the association, occupied the chair, and the Earl of Balfour, K.G., O.M., Chancellor of the University, was the principal speaker. The chairman at the outset stated that the suggestion for the formation of an Alumni Association had been made about a year ago in consequence of the great benefits which had resulted from the founding of similar associations in America. Up to the present time 842 graduates had joined the association, and it had received subscriptions to the amount of £1,075. The latest gift, received that day, had been one of £1,000 from Dr. Charles M. Cooper (San Francisco), of which the yearly interest was to be paid to some assistant in the University Medical Department in order that he might make himself familiar with different lines of medical research and act as practical adviser to young graduates and undergraduates who desired to do some research work. Lord Balfour said that he rejoiced to have an opportunity to address representatives of the University, with which he was so closely connected on a subject which he was convinced was going to have a growing success. It seemed to him that they were too often inclined to consider a university as merely a mechanism for imparting a certain amount of learning and for giving an equipment for future success in life to the student. That, no doubt, was its primary object and one of the greatest purposes a university could fulfil. If it did not fulfil that object, certainly it would not deserve the name of a great

centre of education; but he thought that another general proposition ought to be admitted—that a man who extracted only this amount from his university training was one of the most unfortunate children of that university. A university ought to give much more, and it habitually gave much more, than those bare accomplishments which could be tested by examinations. Anyone who had been through a university would find that after all it was the human intercourse that accompanied instruction, the intercourse between pupil and teacher and the intercourse, at least as much, between fellow pupils, the sensations of union, patriotism, and love of the community of which for some years they were members, that combined, and ought to combine, into the feeling inseparable from each man's view of his own career, and inseparable from love of country and love of home, to help him to serve all the causes to which in the course of his life he might find himself attached. Could it be doubted that if an institution like that, which had had the most admirable effects in the United States, were introduced in Edinburgh, it would be doing a great work for the present and future of the University? Members of the University of Edinburgh were drawn from all parts of the globe for their education, and again scattered to all parts of the world, and carried with them some fragments of those higher things that they had learned within its walls. If an organism were given to these men scattered all over the habitable globe—a living organism which would be a bond of union between those who had left the University and also between them and those who were still either students or teachers carrying on the work of the University—it would be a great advantage to those institutions in their country to which the higher life of the country owed a great debt. That was the main object of the society which had been founded. Another object was the money side of the question; no large sums were to be asked of any member of the society. In fact, the sum asked for was deliberately kept within the resources of those whose means were very small, although he hoped that the obligatory sum would in many cases be exceeded, and that those who were prosperous among the alumni would not be slow to remember the source from which, without doubt, they obtained much of the strength, knowledge, and training to which their success was due. He laid stress on this because he was convinced that even now the general public of this country did not fully appreciate the needs from which the universities inevitably suffered. The cost of teaching had greatly increased, and the cost of research had been added to it in every university worthy of the name. Literature, mathematics, history, philosophy, and theology could be taught without any great cost of apparatus, although it was necessary now to have buildings adequate to the dignity and importance of the work which the university had to accomplish, and such buildings could not easily or cheaply be obtained. When, however, they turned to the experimental sciences and to medicine the cost of teaching was found to be inevitably growing, and, so far as he could see, was inevitably going to grow. These things could not be done cheaply, and without pecuniary assistance modern research and teaching could not be effectively carried on. So much change had taken place in science that even the language used by physicists in 1925 had no resemblance to the language used by physicists thirty years ago. The progress had been revolutionary, and he believed that those who could speak with more authority than himself in regard to medicine would say that, though the changes had not been so revolutionary as the changes in physics, they had nevertheless been of a similar character, and from the mere fact of their being so, they had created an immense volume of merely material assistance. He confessed that he envied their friends on the other side of the Atlantic, who appeared to have an unlimited number of millionaires, prepared to spend their millions, and to come forward time after time to help the good cause of scientific research. He wanted everyone who heard him to feel that this monetary task could not be wholly accomplished either from existing endowments of universities, contributions of Governments, the help of local authorities, or by students' fees. The University had the right to ask those who were not millionaires, and especially those who in their time had

gained all that the University had to give them, to contribute according to their means to the task whose outlines he had endeavoured to draw. Sir Alfred Ewing, Principal of the University, in moving a vote of thanks to Lord Balfour, said it appeared to be increasingly the case that the main concern of a principal of a university was with finance—the getting of money and the spending, or rather the not spending, of it. In his pessimistic moments he thought of the University as a big balance sheet, or as a sheet which would never balance, and it was a relief to hear Lord Balfour say that after all the University was an organism with a soul.

#### REDUCTION OF SCARLET FEVER.

A circular has been issued by Dr. W. Robertson, M.O.H. for Edinburgh, to practitioners in that city, pointing out that the cost of treating cases of scarlet fever last year in the Municipal Hospital was £20,000. Of the cases notified 92 per cent. have received institution treatment. He suggests that the infection of scarlet fever can be controlled with comparative ease, if contact between infected and non-infected persons is avoided, and if inoculation and swabbing (Milne treatment method) be adopted as a preventive. As a result of his previous experience in Leith, he maintains that when this form of treatment was employed the numbers admitted to hospital fell from 83 per cent. to 65 per cent., and he tells of a series of 200 consecutive cases of scarlet fever treated in their own homes in Leith, the largest proportion of which were working men's dwellings, and among which not a single instance of spread of infection took place among other members of the different families involved. The instructions given for this form of home treatment are to swab the throat with carbolyzed glycerin (1 in 10) every two hours for the first twenty-four hours, and for the first four days to anoint the whole surface of the body twice daily with ordinary eucalyptus oil (undiluted); thereafter the anointing is continued once daily for the ensuing ten days.

#### HUMAN NATURE THROUGH THE DOCTOR'S EYES.

A popular lecture with this title was delivered on January 6th, under the auspices of the Philosophical Institution, in the United Free Assembly Hall, Edinburgh, by Dr. Habberton Lulham; the chair was occupied by Lord Sands. Dr. Lulham spoke of the attitude of the general public towards the doctor, enlivening his discourse with amusing anecdotes. He said that if a doctor were to allow himself to be emotionally affected by all the distressing things he saw, he would soon become a nervous wreck. What he had to do was to convert pity into help. The regrettable thing about cases in which nerves were not under control was that nowadays every little condition of nervousness, lassitude, or self-indulgence in its many forms was known as neurasthenia. As a means of getting rid of slight disorders, he firmly believed in making people laugh at themselves. It might be rather a mirthless laugh to start with, but if they would persevere they would find the method had a wonderful effect. He did not believe that nerves out of control were due so much to the rush and hurry of modern life as they were to the increased ease and luxury which people now demanded. He was afraid people did not stand adverse circumstances nearly so well as they used to do. The reason was that they did not make themselves stand the minor troubles enough, without running off for sedatives. Whatever else might be wrong with neurasthenics, there was too much ego in their cosmos.

#### EDINBURGH EXPERIMENT IN THE HOUSING PROBLEM.

An inspection was made on January 13th by the Lord Provost, Sir William Sleigh, and other members of the Edinburgh Town Council of a group of new houses that are being erected on the north side of Edinburgh in Clark Avenue. These constitute a housing scheme on community lines, the City Corporation acquiring and preparing a site for the houses, finding the money, partly from the Government subsidy, to pay the cost of their erection, and giving possession to the tenants. The latter are required to contribute an initial sum of £100 and thereafter to make annual payments of about £30, representing interest and

instalments of capital, for a period of twenty years. After this the house becomes the tenant's absolute property and the title-deeds are handed over to him. By this arrangement the municipality assumes responsibility until the payments are completed, and thus a considerable amount of expenditure in respect of titles, bonds, and capital is saved. The houses consist of five rooms with kitchen and bathroom, and cost, including the price and preparation of site, about £650. Of this amount, £75 is contributed by the Government, £50 by the Corporation, and the remainder through deferred payments by the tenant and ultimate proprietor.

## NEEDS OF SCOTTISH HOSPITALS.

(Continued from page 190.)

THE Committee appointed by the Scottish Board of Health to inquire into the inadequacy of the hospital service in Scotland resumed its sittings on January 20th at the offices of the Scottish Board of Health, under the chairmanship of Lord MACKENZIE.

Mr. JAMES THOMSON gave evidence on behalf of the Glasgow Royal Maternity and Women's Hospital. He said that in the Glasgow Royal Maternity Hospital there were 114 beds, and they had had in the hospital as many as 170 cases at one time, while the average for the last year was 135. They had not refused any cases, but the hospital was certainly overcrowded. A great many more young mothers were thrown into hospital than would otherwise have been the case on account of the housing shortage. They hoped to make better provision by an addition which would add about forty or fifty beds. He thought that the normal cases might be dealt with through the establishment of another hospital in the town, and the maternity hospital might occupy more or less a consultant position. He did not think that patients should pay at the Maternity Hospital, for paying patients could be better treated in small homes. The Glasgow Royal Maternity Hospital was supported voluntarily, and workers' contributions amounted last year to £3,086. If the State chose to give the hospital a payment per case, the managers would have no objection to receiving it.

Professor JOHN GLAISTER (Glasgow), who for twenty-four years has been on the board of the Glasgow Royal Infirmary, next gave evidence. He said that at the present time and in view of existing legislation no provision required to be made for the well-to-do classes nor for those who were designated under the Poor Law the poorer classes. The chief demand for hospital facilities came from the so-called working class, and one of the chief reasons for this was the lessened reluctance of persons to enter hospitals. During his fifty years of association with medicine, as a student and practitioner, he had seen the desire for hospital treatment, and especially for surgical operations, develop greatly. Accommodation in Glasgow fell short of the desires and needs of claimants for treatment, and if a large new general hospital should be established its beds would be quickly filled. The present number of beds at the disposal of persons requiring urgent treatment nearly met the needs of the city, and he thought that the pressure in the ordinary voluntary hospitals could be relieved by the establishment of auxiliary hospitals and by the greater utilization of convalescent homes connected with the large infirmaries. A scheme had been in contemplation for the institution of an auxiliary hospital as a private venture at a cost of about £80,000, and an option had been obtained for a site not more than four or five miles from the city, but it was proposed to wait meantime and see what would develop. He thought that the consensus of opinion in regard to the Royal Infirmary was against the policy of admitting paying patients into the wards. During 1923, as in previous years, the bed accommodation of the Royal Infirmary had been taxed to its fullest, and the number of patients had always exceeded the number fixed for healthiest occupancy. There was no ground left within the present infirmary boundaries for further extension. He thought that more provision than hitherto should be provided by local authorities of large populous centres for cases of surgical tuberculosis, and these, if possible, should be sent to hospitals situated in a country area. He thought also that employers and approved societies might undertake some work with special reference to occupational disabilities, and an institution fitted with mechano-therapeutic appliances, electric baths, radiant heat applicators, and the like would prove a great help in expediting the recovery of workers who had received injuries in the course of their employment. With regard to Poor Law hospitals, he thought that the time had come to utilize whenever possible the accommodation available in hospitals atill under the Poor Law for the needs of the general community. He could not see any objection to grants being given from State funds towards helping voluntary hospitals in difficulties, provided that the State would demand only such supervision of the accounts as would enable it to see that money so given was properly expended, and he did not think that the State should ask for representation on the boards of such institutions. He thought also that, seeing the voluntary hospitals admitted for treatment insurance patients, voluntary contributions from insurance funds would be welcomed from approved societies; and there could not be a better way of expending profits, intended by the Insurance Acts to provide additional benefits to the insured, than by annual contributions to hospitals, graduated in amount according to the benefits received by members of these societies from hospital treatment. He believed strongly in voluntary effort in the support of

general hospitals, and the working classes of the West of Scotland had, as the result of systematized and continuous appeals, responded well in contributions. With regard to the amount of hospital accommodation required in Glasgow, he said that it would be necessary to depart from the old standard of one bed per 1,000, as it seemed to him that one bed in 600 or 800 was the proper estimate for a population like that of Glasgow. He believed that they still had untapped sources for obtaining voluntary contributions.

Sheriff G. L. CROLE, K.C., one of the managers of the Edinburgh Royal Infirmary, said that as regarded that hospital the number on the waiting lists for last year gave an average of 1,812 cases, although 45 per cent. of these were cases on the list of the ear, nose, and throat department awaiting the removal of adenoids and tonsils. Even with this deduction, the numbers remained higher than the managers cared to see, though it should be kept in mind that the Royal Infirmary of Edinburgh might be regarded as a national rather than a local hospital, since practically 50 per cent. of the patients in the wards came from outside the city. With regard to auxiliary hospitals, the Royal Infirmary was fortunate in having provided for it the Astley-Ainslie Institution, a first-class hospital of this type. At present only 34 beds were available, though the accommodation would increase. With regard to the other type of auxiliary hospital, where the simple forms of operation and treatment for a district could be carried out, the position presented difficulties, professional staffing being the chief of these. This, however, could be arranged by having a competent visiting staff. He was of opinion that it would be disastrous to disturb the system on which all the large hospitals had hitherto been maintained. The opportunity afforded to all classes of the community of aiding in the work by contributing according to their means must be regarded as a national asset. When he joined the board of this hospital fifteen years ago the employees in public works contributed only £2,345, while for the past year the amount that was so subscribed totalled £37,950. He did not think that any system of State aid would work satisfactorily alongside the voluntary system so far as Scotland was concerned. The time to ask a man for contributions was while he was well and working, not when he was ill with income reduced. Continuing, he said there was no doubt that the provision for maternity cases in Edinburgh was not adequate, and he thought a new maternity hospital was urgently required, while the old maternity hospital was conveniently situated for being a child welfare centre. He thought that the new maternity hospital should be in close proximity to the Infirmary. He thought that Craigleith Poorhouse might be transferred to the public health authority as a hospital auxiliary to the Infirmary. This was taken over it would, with the provision of ample accommodation for all sick.

Mr. A. K. RODGER and Mr. GEORGE LAIDLAW jointly gave evidence on behalf of the Victoria Infirmary, Glasgow. They said that while this Infirmary had 260 beds there was a waiting list of 333, but they contemplated building an addition to the Infirmary which would pass through about 1,500 patients each year. It was suggested that one of the ways in which the State should contribute towards voluntary hospitals would be to allow sums given voluntarily to hospitals to be free from income tax and death duties.

On January 21st the Committee took evidence mainly in relation to hospitals designed for the treatment of children. A statement had been prepared by Mr. Robert Barclay, honorary secretary and one of the directors of the Royal Hospital for Sick Children at Glasgow, which was described as the largest hospital devoted to children in the United Kingdom.

Mr. BARCLAY stated that there were now three hospitals in Scotland—at Glasgow, Edinburgh, and Aberdeen—entirely devoted to children. The Royal Hospital for Sick Children in Glasgow dealt with children up to the age of 15 years, and had accommodation for 275 patients. Extensions and additions were in progress which would make up the available beds to 350, and would provide a new out-patient department, an orthopaedic department, an enlarged electrical department, a milk department, and a department for the manufacture of medical and surgical appliances. The accommodation at the convalescent branch was to be doubled. The cost of these schemes was put at over £100,000, and an appeal, which had been issued four months ago, had resulted in the whole sum being subscribed with the exception of a few thousand pounds. The importance of the housing question in relation to children was adverted to, and this witness considered that improvement in this direction would reduce the supply of patients. The continuation of the voluntary principle was advocated, and he thought that, subject to a little rivalry, which was healthy, it was right that the large hospitals in a city should co-operate with one another. With regard to State grants, he thought that these should be apportioned between England and Scotland according to population, and not according to financial strain; and he thought that additional State aid might be given in respect of teaching and research work, which was national and not local in character; and which would not compromise the voluntary principle. He thought that before further hospital accommodation was required suitable provision should be made outside the hospitals for chronic cases, incurables, and cases of tuberculous disease, which were apt to occupy hospital beds unduly. Referring to the English method of treating paying patients alongside non-paying patients, the witness said that this was not desirable in Scotland, and could not be done without causing serious difficulties. He was, however, in favour of paying wings in hospitals, provided the paying part was quite distinct and that it could finance itself. The witness referred to the question of milk supply, which he said was closely allied to

tuberculous cases. It was vital to children that the supply should be pure, plentiful, and cheap, for at present it was undoubtedly the source of tuberculous infection, and its distribution was far from hygienic. He thought that the whole milk trade should be under the careful and systematic supervision of the Health Department or the local authorities; that the sale of milk should not be competent except from a licensed source and by a licensed dealer, and that dairies should be under central supervision.

Mr. W. J. GINSON, chairman of the managers of Fnlkirk Infirmary, gave evidence with regard to hospital accommodation in the Fnlkirk district. They had at one time taken in patients on a paying basis, but this had to be abandoned because of the great numbers of ordinary patients demanding admission. They were, however, convinced that it would be desirable to try and provide private accommodation, for which a considerable number of people would be willing to pay. He thought there ought to be some curtailment of the present overlapping of appeals for subscriptions, for while their district contributed £3,000 yearly to the infirmaries of Edinburgh and Glasgow, the local hospital received only about £5,000, and he regarded these sums as disproportionate.

Mr. THOMSON, chairman of the Stirling Infirmary managers, stated that they were aiming at building an entirely new infirmary at a cost of £70,000, and in five weeks they had got £26,000, which showed a great interest on the part of the people of Stirling and district. He was confident that the amount required would be raised by voluntary effort, and, in this connexion, he was in favour of decentralization, and thought that more cases should be treated in Stirling instead of being sent to Edinburgh and Glasgow. He did not approve of taking money from the rates, especially in view of the conditions that prevailed just now with regard to voluntary assistance. There was no provision at present in Stirling for maternity cases, but the managers of the Infirmary intended to make provision for this purpose.

The Rev. Dr. MONTGOMERY CAMPBELL, representing Dumfries and Galloway Royal Infirmary, considered that the voluntary system ought to be continued, encouraged, and developed, and in the district of Dumfries it had amply met the necessities of the case. At the present time, however, there was an insufficient supply of beds, and, while there were nominally 113 beds in the Dumfries Infirmary, the average number of patients constantly in hospital during the last year had been 106. It was urged that immediate steps should be taken to provide more beds and the appropriate staff accommodation. He believed, as the result of long experience as a parish minister, that an element in human nature was evoked by service in the present type of voluntary hospital which would not be evoked by another class of hospital to the same extent.

The Rev. W. S. MATHESON, representing the managers of Galashiels Cottage Hospital, said that this hospital was originally intended to meet the needs of Galashiels, but in the last few years cases had been taken in from surrounding towns, and they would have to provide increased accommodation and consider other extensions.

At the sitting of the Committee on January 23rd a plan was submitted by Mr. W. E. Whyte, district clerk, Hamilton, which would allow for State aid without State control. The memorandum runs to 39 printed pages, and refers particularly to the hospital needs of the county of Lanark, a district which, the author of the memorandum pointed out, is the most important in Scotland so far as population and valuation are concerned.

According to Mr. Whyte's evidence, over 70 per cent. of the houses in the district are one or two apartment houses, and the housing conditions are described as so deplorable and inadequate that institutional provision for the treatment of most diseases is obviously necessary. He considered that real co-operation between local authorities was seldom practicable under present conditions, and he had in view the extension of the functions of the public health authority, but he would not advocate the granting of power to public health authorities by legislation for the establishment of hospitals for the treatment of general diseases. He would, however, advocate co-operation between the rate-aided authorities and voluntary authorities. As the capital cost of the additional institution necessary would be very great, he thought the State should set aside a sum from which capital grants to approved institutions would be made, such fund to be under the direction and control of a central body. For dealing with tuberculosis he considered there were two ways in which children might be treated: either by an extension of the Hairmyres Colony, which at present existed, or by the introduction of the Grancher system, which had been working for some twenty years in Paris, and had consisted in placing out in healthy rural families children whose health was jeopardized through living with tuberculous members of their own family. In Paris, out of 2,300 children so placed out, only 7 had developed tuberculosis. The witness thought that the voluntary system should be maintained at present, but whenever the need was such that the voluntary system could not cope with it it was the manifest duty on the part of the State to make good the deficiency. This could be ascertained by obtaining periodical returns from the various institutions.

Lady SEAR GUNDOER gave evidence on behalf of the council of Queen Victoria's Jubilee Institute for Nurses (Scottish Branch). She said that 600 additional nurses would be required to establish a complete home nursing service for Scotland. This would make a total of 1,500 nurses so employed, and the provision was entirely a question of finance. At present voluntary contributions amounted to £120,000, and a full service could be provided by an annual

grant of £60,000. A head of the population of Scotland, which would yield £122,000. Both the preventive and the curative work of a nurse, who went about in the homes of the people, restricted the development of illness, and consequently the necessity for hospital treatment. The possibility of after-care in the home, which was given by adequate nursing, also shortened the time necessary for the occupation of hospital beds. A proper system of co-ordination between hospitals and local nurses by means of cards indicating treatment required would undoubtedly save pressure on hospital accommodation. About 20 per cent. of the cases attended by the Queen's Nurses throughout Scotland were treated in lieu of hospital accommodation. With a full nursing service for the whole country at least 100,000 cases would be nursed in the course of a year, and from these figures it would be seen that under the scheme suggested there would be an annual saving of hospital accommodation for 32,000 cases. The witness thought that the cost of a really good nursing service in Scotland would be about £300,000. A great deal of work was done for public authorities at the present time, but little or no help was received from corporations. She did not think they could have a complete nursing service in Scotland by the voluntary system.

The Committee adjourned till the following week.

## Correspondence.

### LONG FREEDOM FROM RECURRENCE AFTER OPERATION FOR CANCER OF THE BREAST.

SIR,—I have read in your issue of January 24th (p. 156) with interest the notes by Mr. F. J. Steward of a case of recurrence of cancer of the breast after an interval of thirty-one years from the time of operation.

Some years ago I operated on a case of recurrence twenty-four years after operation. The right breast and the axillary glands were originally removed by Sir Thomas Smith for a typical scirrhus cancer, and I saw the patient with him after an interval of twenty-four years of good health. She had then recently developed a small lump in the skin, two inches below the middle of the right clavicle, and there was also a hard gland above the clavicle. I removed both of these, and the microscope showed typical breast cancer. A further examination while the patient was anaesthetized revealed hard tumours in each ovarian region, and she died within a year with growths in the cervical glands and visceral dissemination. The facts that the recurrence was in the skin of the chest and that it was typical breast cancer leaves no doubt that this was a case of genuine recurrence of the original tumour, and not of an independent new growth originating in breast tissue left behind at the first operation.—I am, etc.,

London, W., Jan. 6th.

ANTHONY A. BOWLEY.

SIR,—Mr. F. J. Steward's case of recurrence of cancer of the breast thirty-one years after operation is somewhat analogous to a case published by me in your issue of June 24th, 1922 (p. 995). In the latter case the tongue had been excised for epithelioma in 1888. There was no recurrence near the site of operation and the patient lived a healthy hard-working life until 1922, when he died of cancer of the cardiac end of the stomach. This diagnosis was verified by *post-mortem* and microscopical examinations. I agree with Mr. Steward in his closing paragraph, where he states that the exciting cause in such cases must be general rather than local. They also go to show that a previous attack of cancer cured (in the ordinary sense of the term) by operation does not give immunity to another attack later on in life.—I am, etc.,

Warrington, Jan. 26th.

J. S. MANSON.

### TREATMENT OF PERFORATED GASTRIC AND DUODENAL ULCERS.

SIR,—I am heartily in agreement with your correspondents, Mr. Zachary Cope and Dr. Tonking, who do not consider that it should be generally accepted that gastro-enterostomy must be performed at the same time as the closure of the perforation in this type of abdominal catastrophe. On this question they are at variance with the recommendation of Mr. Percival Mills, whose experience favours the double operation. The reason for my opinion is not that I do not realize the excellent results of

immediate gastro-enterostomy, but because I believe that the routine treatment of a surgical emergency should be strictly in accordance with the emergency and not necessarily directed to the cure of the primary condition. Furthermore, surgical emergencies should be amenable to simple surgical remedies, and Dr. Tunking, I think, sounds a true note when he states that "for the general practitioner surgeon simple sero-serous suture and oversewing of the omentum is the safest course." It is the essential treatment of the perforation, together with dry sponging of the soiled peritoneal cavity. This treatment is on all fours with that applied to acute intestinal obstruction. Relief of the obstruction is then the immediate objective of the surgeon called upon to operate in a hurry.

Mr. Cope says that he used to be in favour of the combined operation, but that he now thinks that it is only occasionally advisable. This seems to me a subject on which a surgeon of experience may well have changed his mind. To such a one all things are lawful, but all things are not expedient. Expediency should be the governing principle in the surgery of acute abdominal diseases. The two main factors are the condition of the patient and the capacity of the surgeon. Time has a bearing on both: the hours that have slipped away before the perforated patient reaches the operating table, the minutes that will be consumed by the operation. For every hour over eight that elapses before the operation is done the mortality rises. For every minute that the operation is prolonged we ought to be sure that the patient gains some advantage. Anastomosis adds from twelve to twenty minutes to the length of the operation. Obviously, then, gastro-enterostomy is inadmissible in late perforations with widespread peritonitis, or where the condition of the patient is poor.

The other side of the picture, however, should be clearly viewed, and I must admit that here I differ from Mr. Cope, and I find more cases suitable for immediate gastro-enterostomy than I used to. My reasons are twofold: one is that cases treated by the double operation do undoubtedly have a very easy convalescence, but even more am I impressed by the number of cases of successfully sutured perforations which require surgical treatment at a later date. Gastro-enterostomy at the time of the operation for perforation is usually much easier of performance than anastomosis when the ulcer is closed, but the stomach or duodenum is surrounded by dense adhesions.

A long view of the treatment of perforated ulcer of the duodenum and stomach must include both the immediate and remote results. An opportunity occurred to me during a "major week" at St. Thomas's last year—when we had five perforations in the ward at the same time—of giving a simultaneous trial to the single and the combined operation. Three of them lived and two died. The age of the patient is one of the important factors, and the fatal cases occurred in patients whose ages were 59 and 63 respectively. The recoveries were all in younger patients. The age of the perforation is even more important, and in the fatal cases operation was not performed until twenty-four hours had elapsed, and in one of them it took place forty-eight hours after the perforation. The three surviving cases had perforated for five, six, and fifteen hours respectively. Two out of these three cases had immediate gastro-enterostomy and the ulcers were of the juxtapyloric type, where anastomosis yields such good results. I do not for one moment believe that the fatal cases would have been saved by the double operation. One died the next day, and the other from bronchopneumonia with a dilated heart eight days after the operation. Of the recoveries the quickest was actually in the case where only suture of the perforation was done, and he left hospital for a convalescent home ten days later; the other two left after seventeen and eighteen days respectively. Up to the present time, eight months from the date of operation, all three are in good health, but the future alone will show the benefit of the short-circuiting operation.

If we look at the remote results of simple suture of a perforation I think the old theory that such a complication cures the ulcer is completely exploded. It is about as true as the fiction that an appendix abscess destroys the

appendix. It may be urged that the operation for the ulcer should be performed when the patient is convalescent from the first operation. It must be remembered, however, that we operate on human beings, and one of their characteristics is to dislike operations. Such has been my experience that I am accustomed to teach that at least 15 per cent. of former perforations require surgical treatment for persistent, or recurrent, dyspepsia. The combined operation, I believe, will do much to wipe out this undesirable figure. We may, however, see some patients back again with jejunal perforations, for there is a type of recurrent perforator difficult to eliminate altogether.

As I have stated at the beginning of this letter, which is perhaps too long already, I do not think gastro-enterostomy should be part of the routine operation for perforation. If circumstances of surgeon, anaesthetist, and patient are all favourable it is time well spent, but the superiority of the double operation over simple closure as an emergency operation can only be that the stomach gets rest. Immobility of the affected area—most often the region of the pylorus—for twelve hours is probably all that is necessary, and the chief value of the immediate anastomosis is that it reduces post-anaesthetic vomiting to a minimum, and indeed it often abolishes it altogether. An efficient gastro-enterostomy done for any particular lesion has this great merit, and in that way it will no doubt lessen the mortality of perforated gastric and duodenal ulcers from haematemesis or secondary perforation. These are, however, very rare causes of death after suture. Most fatal cases die from bronchopneumonia, peritonitis, or subphrenic abscess and its sequels. Rest to the stomach can be secured long enough to heal a sutured ulcer by good anaesthetization, and rectal saline feeding for the first twenty-four hours.—I am, etc.,

London, W., Jan. 19th.

JOSEPH E. ADAMS.

### SHAVING THE VULVA.

SIR,—At times we have as many fashions in medicine as ladies have in dress, and the *raison d'être* for some of the medical fashions, I fear, has as little substance as the fluffs and flimsies that go to make up feminine adornment. One of the medical fashions recently promulgated is to have the vulva shaved during labour, and we find obstetricians strenuously urging what they consider the absolute, imperative necessity for adopting this procedure. So far I am afraid I must own to being a heretic with regard to this new medical doctrine.

The first, but by no means the most serious, objection to this performance is that it must cause a distinct shock to the average woman's modesty. Here is the way I look at the matter. I am thoroughly convinced that every organ and every part of the body has its own special function. Luckily, in late years patient investigations have made known to us the part played in the human economy by many organs which previously were regarded as mere anatomical items. Take, for instance, the endocrine glands, which are now known to exercise a potent influence over our physical well-being. Only a few years ago the appendix, too, was regarded as a perfectly useless organism, a sort of anachronism. Now we know that it has important work to do, and does it. Before its function was discovered a friend of mine, an expert surgeon, always, on opening the abdomen, no matter for what purpose, laid hands on the appendix and, in spite of its being quite healthy and inoffensive, ruthlessly swept it away.

Pondering over these things I have been asking myself, Are the vulvar hairs mere purposeless appendages, or do they fulfil any useful function? And I am convinced that they perform at least two very important duties. They are these. During menstruation they convey away as far as possible from the body the menstrual fluid, which is meant to be a waste product, and they act similarly with regard to the lochial discharge, which is also a waste product. In this connexion it is worthy of note that the vulvar hairs are more or less non-existent till the time arrives for the performance of these two functions. They are not developed till puberty—the time at which the first menstrual flow occurs—and, of course, the girl child

## CORRESPONDENCE.

cannot come into labour until after puberty. Now let us see what occurs with regard to the lochia when shaving has been done. The discharge, instead of being conveyed a distance from the vulva, remains on it and becomes caked, thus forming splendid pabulum for the hungry and migratory bacteria that are bound to be in the neighbourhood, and we all know that well fed bacteria increase and multiply with great rapidity. On the other hand, it may be urged that when shaving has not been done clotting might occur on the hairs. No doubt. But the tapering shape of the hairs, the fluidity of the lochial discharge as it emerges from the vulva, and the force of gravity has tend to prevent that clotting till the discharge has traversed a distinct distance from the bacteria can travel along the hairs, executing a sort of tight-rope dancing.

I am a thorough believer in Listerism, and accordingly would say, "Use suitable antiseptics certainly, but let the razor test peacefully in its case." And instead of keeping the woman glued to the bed in the horizontal position for days and days, as was the fate of our mothers and grandmothers, allow her to sit up gently from time to time to promote drainage, which will be facilitated by the vulvar hairs. If that is done I feel confident that we will have gone a long way on the road towards preventing that terrible bugbear, puerperal sepsis, the apprehension of the obstetric physician, and we will avoid the slight of being nicknamed the "barber-surgeons."—I am, etc.,  
HENRY CONN.

**PUERPERAL INFECTION.**  
Cork, Jan. 18th.

Sir,—It may be of interest to cite two of my recent cases.

The first, a primipara, was attended by me during her confinement in a nursing home where she got every possible attention. She had a rigor on the second day and died on the eleventh day of septicaemia. Forceps were used when the head was on the perineum. There was a slight tear which required one stitch.

The labour was a long one, lasting some thirty-six hours. She was My second case, a 2-para. I have just finished with. She was confined in her own home. She had a labour of some eight hours duration. She also had a low forceps extraction, and also required a single stitch. There was, however, in her case a large congeries of inflamed veins in the vagina on the fourth day after formation, during which the temperature was 102° F., pulse 120.

The abscess ruptured into the vagina on the fourth day after confinement. The infection was *Staphylococcus aureus* and *Bacillus coli*. The patient never looked back—this, although pus was pouring into the vagina and mixing with the lochia.

Now here are two cases. The technique was the same in both. How different the results! The nursing home case, in faultless surroundings, dies. The other, in a working-class home and flooded with pus, puerperal or other. I am of opinion there is some quality inherent in the patient which determines infection, puerperal or other. I have attended 2,550 confinements. My percentage of puerperal infection cases is 0.05 per cent.; these patients all died.

Will the specialists who take us general practitioners to task kindly do two things? First, tell us their own percentage rate of puerperal sepsis and how they explain it. Secondly, will they engage in general midwifery work as we do for two years, practising all the asepsis they advise, and let us know again their percentage of sepsis and explain it. If they are not ready to do these things let them not criticize.—I am, etc.,  
JAMES COOK.

**ELECTRONIC REACTIONS OF ABRAMS.**  
Glasgow, Jan. 15th.

Sir,—I notice that Sir Thomas Horder, when presenting the report of his committee of investigation of the "E.R.A." to certain Sections of the Royal Society of Medicine, referred to the "bigoted and a priori condemnation in which, actually, critics almost exclusively indulged, and of which alone the majority appear capable." I happen to be the only critic personally named in his address, and therefore feel bound to answer this accusation.

The charge of a priori condemnation is rather a superficial one, since it is notorious that the founder and followers of "E.R.A." have taken every precaution to prevent impartial examination of their machines or

methods. The machines are leased at a fantastic price, and under a bond which forbids them being opened. The alternative to buying a machine is to co-operate with electronic practitioners. This, however, is a matter of extraordinary difficulty. In this respect Sir Thomas Horder's committee evidently has had the same experience as all previous investigators, since it appears that it was unable to arrange to test the diagnostic power of "E.R.A." practitioners, subject to the usual condition that the results should be published whether positive or negative.

As regards the charge of bigotry in criticism: I, like many others, have attacked the "E.R.A." practitioners on ethical and scientific grounds. The ethical criticism is that they are exploiting a new form of diagnosis, the value of which has never been established by any form of impartial test, and that they consistently evade any such test. I charge Sir Thomas Horder endorses and emphasizes them—does go further, and suggests that the electronic point of view know that their methods are perfectly willing to use the methods in practice. From the scientific point of view, but that nevertheless they are perfectly willing to use the methods in practice. From the scientific point of view, I consider that the claims of the electronic re- and I agreed with the opinion of the *Scientific American* that there was no evidence to show that the electronic actions even exist. Sir Thomas Horder definitely endorses this opinion as regards the regular followers of Abrams (conclusion 2 in his report). The very interesting positive results recorded by his committee were obtained with Dr. Boyd's "emanometer," and we are told that this instrument is not a minor variation of the "E.R.A." machine, but is "a design *de novo* based on a different conception of the phenomena involved," and that the conclusions arrived at by the committee "leave the position of the practising electronicist as scientifically unsound and as ethically unjustified as it was before."

I cannot see that Sir Thomas Horder has justified his sweeping charge of unfair criticism against previous critics of "E.R.A." Past criticism of "E.R.A." may have been founded on scanty evidence, but this is bound to be the case whenever a new remedy is exploited and its methods are kept secret. Indeed, the charge of "bigoted and a priori criticism" is one of the stock lines of defence of every quack medicine vendor. I consider that it is unfortunate that this particular mode of defence of secret remedies should have received any kind of endorsement from high medical authority.—I am, etc.,  
A. J. CLARK.  
University College, London, Jan. 24th.

Sir,—The members of the Society of Electronic Medicine in London desire to submit to your notice the following commentary on Sir Thomas Horder's recent address on the electronic reactions of Abrams delivered before the Royal Society of Medicine.

It should be stated by way of explanation that this commentary, which is somewhat critical, is not to be understood as attempting to detract in any way from the value of his communication or as throwing any doubt on the sincerity of the scientific spirit prompting him to make it.

The value referred to lies, of course, in the fact that Dr. Boyd of Glasgow has succeeded in satisfying Sir Thomas Horder and his co-observers that an electronic reaction exists, for which achievement the former deserves no little praise; but more than this bare fact the interested committee is apparently not prepared to regard as demonstrated.

The statements, therefore, to which we are bound to take exception in Sir Thomas Horder's address concern only what by his own admission he knows as yet nothing about—namely, the practical value of Abrams's ideas in the field of medicine; and we note with regret that these statements are made with no less assurance than he displays in connexion with the experimental work of which he is certain.

We make no comment upon certain pronouncements, which, although they are to be found in the text of what has been termed "the full report," were not embodied in the actual address itself, but confine our remarks solely to

the latter as reported in the columns of the *BRITISH MEDICAL JOURNAL* of January 24th, 1925.

There a statement is published of such a nature that we, as a society, cannot but request Sir Thomas Horder either to assure us that owing to misinformation he has been in error or to produce satisfactory evidence supporting it.

This statement is to the effect that to employ Abrams's treatment is "scientifically unsound and ethically unjustified." The only reason he gives for making it is the fact that the scientific basis of the treatment remains uncertain; but while this is undeniably so, we must point out that no such objection can validly be made to the employment of a treatment which has been proved to give good results. If Sir Thomas Horder were to be taken at his word in this matter of ethics, then *ipso facto* a host of useful therapeutic measures would necessarily stand condemned in his eyes, including no doubt several hitherto employed by himself. Indeed, we should have to conjure up the curious vision of this busy physician "only experimenting privately" with methods the scientific rationale of which is still obscure to him—surely a *reductio ad absurdum*! We therefore are curious to know what real justification, if any, he can plead for taking up so extraordinary and autocratic an attitude.

In a communication to the *BRITISH MEDICAL JOURNAL* of January 10th (prior to Sir Thomas Horder's address) a member of our society took the trouble, in view of widespread misunderstanding, to dispose of all possible grounds of accusation on the score of unethical conduct. Facts were stated showing that the society had not made exaggerated claims on behalf of the Abrams system, and that they had taken all possible steps towards removing the mystery associated with it by a certain body of individuals to whom, and to whom only (also on account of their exaggerated claims), the derogatory term "Abrams cult" could be applied. To say that no definition of a "genuine Abrams worker" was afforded by that communication is so transparently inaccurate that anyone interested can simply be referred to it to discover the truth for himself.

It must be admitted that Abrams himself was not, according to our ethical ideas, free from the blame attached to the cult which sprang up as a result of his conceptions, but in our view his extraordinary temperament (common enough in geniuses) and the opposition he had to face ought to be taken into consideration when we condemn him for his mistakes. All who knew him intimately believed him to be honest, and at any rate he seems to deserve greater credit for his ideas than Sir Thomas Horder is inclined to give him.

In a letter to the *Lancet*, February 16th, 1924, the same member of our society said, "However interesting a general correspondence between 'E.R.A.' and clinical findings may be, it would be surprising to discover that they absolutely fitted in with one another." This letter, which in every way reflected the cautious view of Abrams's claims taken all along by our society, also stated, "The first reply to the criticisms of 'E.R.A.' lately begun in the *British Medical Press* contains an offer to have the results of treatment along one important line publicly investigated; and the spirit of this offer has but one significance—namely, that Abramsites desire only to maintain a faith based on reality." This offer at the time was not deemed worthy of acceptance.

If to these observations we add one to the effect that medical journals have experienced difficulty in finding room for our communications, little significance can be attached to Sir Thomas Horder's complaint, "neither coaxing nor baiting nor even sincere invitation has induced practising electronists in this country to tell us exactly what they are doing."

Statements we have made in the past (some nearly a year ago) indicating a moderate attitude cannot be construed as "belated misgivings," nor are we prepared to admit the parallel of "turning King's evidence" either in respect of "turning" anything at all or in respect of identifying Sir Thomas Horder's authority with the high authority implied by this well known phrase.

As for the idea of no "electronist" being public-spirited enough to acknowledge the "glaring inconsistencies" in his work, we suggest a very cogent reason why publication of

certain tests was deemed "inadvisable pending further research." It is that our researches (apart from treatment results) have not yet enabled us to say more than that an as yet undefined relationship exists between "reactions" and disease. We cannot at present do more than use these reactions as general indications guiding treatment in conjunction with other ordinary and "orthodox" indications. We must point out that frequent examination of a patient's blood reduces the chances of our being misled through the interference of factors at present beyond our control, and if we check our findings by clinical examinations it cannot be said that we are likely to make more mistakes than the average physician. "Tests," on the other hand, involve one or few examinations of isolated sets of specimens without the help of clinical observation.

In spite, however, of these considerations, from which it may be taken that our accessory diagnostic procedures are far from being mathematically accurate, remarkable diagnostic accuracy under "test conditions" has occasionally been achieved. Special reference may be made to the test to which Dr. Mather Thomson submitted himself, devised by Lieut.-Colonel Tizzard, Major Lefroy, and Dr. C. B. Heald. This test, which resulted in correctly diagnosing certainly three, and possibly four, unknown bloods out of four, was not fully quoted (if even referred to) by Sir Thomas Horder. We hope that Dr. Boyd's inventions may lead to the discovery of a technique enabling this kind of result to be attained more consistently.

Such successes, even if rare, certainly lend weight to our very general claim in regard to the practical value of Abrams reactions. History has shown that men do not wait for phenomena to be accurately understood and controlled before they begin to make what use of them they can.

It should be added that our investigations into the explanatory principles underlying "reactions" and treatment effects have not yet borne fruit, and we do not believe that correlation of certain reactions with specific disease processes has yet been satisfactorily worked out. No statement implying the contrary has had the approval of our society or of its president. All this—which evidences a sincere and moderate claim—was embodied in a communication sent to the *BRITISH MEDICAL JOURNAL* prior to Sir Thomas Horder's address, for which, however, no space was then available. Yet we are said to be "masonic" in our methods!

The chief claim which we, as a body of investigators, make is that excellent results have occurred from the treatment of patients by Abrams's oscilloclast, often in cases uninfluenced by all "orthodox" methods (including the most modern psychic treatment) and generally in organic conditions. The society assumes no responsibility whatever in connexion with a new machine, not yet tested, which has been placed on the market by one of its members (Dr. Laughton Scott) or with his particular theories; but reference may be made to the fact that the cases recorded in his recently published book were treated by Abrams's oscilloclast.

To sum up, our society can see no justification for several statements made by Sir Thomas Horder which have no real bearing on the kernel of his recent communication, nor is it in any way impressed by the appearance of authority with which he attempts to invest his committee, as evidenced by such statements as that their conclusions "give no sanction" for the employment of certain measures in practice by other qualified physicians. We see nothing to justify the view that we have been "manoeuvring for position" any more than Sir Thomas Horder appears to have been doing, and we can assure him that the imminence or otherwise of his address was not a matter the influence of which was in the least apparent amongst us.

His committee is reminded that only in so far as they have been observers of another man's work are they qualified to express guarded opinions on the subject of Abrams's reactions, while on the subject of any diagnostic value they may have or of investigation into the results of treatment they appear to have no justification for expressing any opinion at all.—I am, etc.,

OSCAR PARKES,  
Secretary, Society of Electronic  
Medicine.

London, S.W., Jan. 22th.

## CANCER OF THE OESOPHAGUS.

SIR,—In the discussion on Mr. Souttar's paper on cancer of the oesophagus, in the Surgical Section of the Royal Society of Medicine (reported in abstract in the *BRITISH MEDICAL JOURNAL* of January 17th, p. 115), Sir StClair Thomson raised the important question of the place of gastrostomy in the treatment of this condition; and asked, in view of Mr. Souttar having made only the slightest reference to this mode of treatment, whether gastrostomy was ever required for gullet cancer. Sir Charters Symonds expressed the opinion that the question of gastrostomy did not arise at the present day at the hands of those who were expert at modern intubation methods, as it was possible to deal with any region of the gullet by intubage.

In spite of this authoritative pronouncement by the experienced originator of the first really satisfactory form of intubation apparatus for gullet stricture—the epoch-making Symonds funnel—I am emboldened to express the opinion, based also on large experience, that Sir Charters's pronouncement excluding gastrostomy is too absolute. I admit that there must be few cases, if any, of cancerous stricture of the middle three-fifths of the gullet which cannot be safely and successfully per-endoscopically bougied up and intubated by experienced and skilled manipulators; but I venture to affirm that there are some very tight and tortuous strictures in the supraclavicular gullet above and in the phreno-cardiac portion below where difficulties may be encountered, and where it is safer to resort to gastrostomy, and where there is a very real danger of perforation even in the most expert hands. The same observation also applies to some tight pharyngo-oesophageal and oesophago-gastric strictures. I agree with Mr. Souttar and Sir Charters Symonds that intubation, when it can be carried out, and with safety, is always more comfortable and satisfactory to the patient than gastrostomy, and has the advantage over it that the patient is able to swallow the saliva which is usually enormously increased in gullet cancer.

Radium therapy has a much more restricted field of application than intubation, but in properly selected cases, and when it acts favourably, it has the advantage over intubation or any other form of treatment that it may bring about either temporary arrest of the growth, or marked reduction of the growth, or even apparent gross disappearance for a considerable period, the latter amounting in exceptional cases to several years. Such gratifying results were reported recently by Guisez in his Semon Lecture, and also by me in a paper published in the *JOURNAL* of December 27th, 1924 (p. 1196).

In conclusion, whilst thinking that Sir Charters Symonds, Mr. Souttar, and others rely too much on intubation, to the exclusion of other methods of treatment (in exceptional cases), such as radiotherapy and gastrostomy, at the same time I think that Mr. Souttar's substitution of spiral wire funnels for gum elastic ones promises to be a distinct advance.—I am, etc.,

London, W.1, Jan. 23rd.

WILLIAM HILL.

## A NEW OUTLOOK ON CANCER.

SIR,—Dr. James Young's paper in the *BRITISH MEDICAL JOURNAL* of January 10th (p. 60) is a stimulating statement of facts and of reasoning based thereon. The facts have wide biological and pathological bearings, a few of which I beg leave to indicate.

So long as I left the label "sporozoa" on the alien cell inclusions and alien free bodies of cancer, mollusum, syphilis, etc., I paid but little heed to the finding (whether by others or myself) of bacteria or other fungal forms in cultures made from cancers. This attitude was reversed when I realized that these alien bodies are fungal and are akin to the genus *Synchytrium*.<sup>1</sup>

The group Phycmycetes is now taken to include synchytrians and other Chytridinae, with Mucorineae and other orders of fungi. They have affinities with the Mycetozoa. The stalked sporanges of the common mucors are familiar; as is also the fact that when mucors are cultivated anaerobically in presence of glucose they grow in their gemma-form—that is, like yeast cells—and, like the latter, they cause alcoholic fermentation.

<sup>1</sup> *Lancet*, vol. ii, 1922, p. 495.

From a study of Dr. Young's illustrated paper<sup>2</sup> I concluded that the forms he has described are cultural modifications of the same fungi that constitute the alien cell inclusions, etc., of cancer. In some of Dr. Young's microphotographs plasmon (?=plasmon) is seen to have grown out from the nuclei of cancer cells; I have little doubt that such growth started in pseudo-karyosomes, such as are described in *Protozoa and Disease*, Part ii, Chapter xii.

In water cultures of mollusca corpuccles streaming of amorphous protoplasm is commonly the first visible sign of active life (see *Protozoa and Disease*, Chapter vi). A similar commotion was observed by Löhnis and Smith in the plasmon stage of some of their cultures of *Azotobacter*.

*Synchytrium tarazaci* is the foundation species of its genus. Synchytrians are allied to coecidia and only their coecidium-like stages are described in textbooks, but I have found also a dense chromidial (amorphous) stage.<sup>3</sup> In *S. emboliforme*, the cause of wart disease (Kartoffelkrebs), E. Köhler has described a coccus-like form, which he regards as degenerating; but, in *S. tarazaci*, I have found, and described in a paper as yet unpublished, a quite similar form as the initial stage of the amorphous chromidial modification just mentioned.

The association of a filterable virus with specific cell inclusions is frequent and noteworthy: we should remember that the first demonstration of a filterable virus was in mosaic disease of the tobacco plant (Lysanovski, 1892), also that in this same plant disease cell inclusions occur, which phytopathologists agree in regarding as being of the same nature as Guarnieri's and Negri's bodies.—I am, etc.,

London, Jan. 10th.

J. JACKSON CLARKE.

## HEART STRAIN.

SIR,—The following statement in Dr. Brockbank's very interesting lecture on heart strain (*BRITISH MEDICAL JOURNAL*, January 10th, p. 57) seems to me to be open to considerable criticism.

"The second reason is that the pressure in the aorta, whatever it is, which drives blood through the incompetent valves, acts at its full strength on every part of the interior of the left ventricle of the same area as that of the leakage in the valve, and is not diffused all over the wall of the ventricle. In other words, if there is a force of 100 mm. of mercury acting on a valve leak of 1/4 in. square, there will be a force of 100 mm. acting on every square 1/4 in. of the ventricle, and not 100 mm. diffused all over the ventricle."

Theoretically, of course, this is quite true. Does it then follow that a valve leak of 1/4 in. is more dangerous than one of double the size? Would one of 1/10 in. be more dangerous still? In other words, is the danger in inverse proportion to the area of the opening?

The principle underlying Dr. Brockbank's statement is the old familiar one of the Bramah press, whereby the pressure exerted by a piston working in a tube of small cross-section is conveyed through the liquid in a rigid container to a piston working in a tube of much larger cross-section, and is thereby greatly increased. The considerable distance through which the smaller piston moves, in one or repeated strokes, is, of course, the means by which mechanical advantage is gained in magnifying the pressure.

But three things are here to be noted: (1) There must be no valve opening out of the container; (2) the container must be approximately rigid; (3) time must be given for the liquid to flow through the smaller opening.

None of these data hold good in the case of the heart. (1) There is what is equivalent to another valve opening from the ventricle—namely, the remaining apposed edges of the semilunar valve. These (unless adherent) are only held together by exactly the same pressure as is exerted from the ventricle. In other words, in no case can the intraventricular pressure caused by a partial valve leak be greater than that caused by a complete valve leak. Practically, it must be considerably less, owing to the slower rate of flow. (2) The ventricular walls are, of course, far from being rigid; that is to say, the "give" at any one part will take off the pressure, and so prevent the full theoretical pressure being exerted until the tension is very high. (3) The rate of flow, being much slower through a smaller

<sup>2</sup> *Edin. Med. Journ.*, 1924, p. 163.

<sup>3</sup> *Lancet*, February 16th, 1924, p. 351.

opening, renders it impossible for a dangerous tension to be exerted during the small period available in diastole.

From these considerations I think it is apparent that theoretical estimations have little place in reckoning up the danger of an incompetent aortic valve. The utmost danger would be found if the whole valve were deficient—that is, if the opening were at its maximum width.—I am, etc.,

Grangemouth, Jan. 17th.

THOMAS PULLAR.

#### FREUDIAN DOCTRINE.

SIR,—Criticism of the body of doctrine known as psycho-analysis is undoubtedly needed. But if such criticism is to be of any scientific value it should be both informed and constructive. Informed criticism can come only from those who have become practically acquainted with the method by carrying out a number of prolonged analyses on patients—and, still better, who have also submitted themselves to prolonged analysis under the direction of an experienced analyst. Constructive criticism can come only from those who have accumulated a wealth of clinical data by this same method of "deep" analysis, only to be acquired by many years of experience.

The number of psycho-therapists in England outside the ranks of the avowed Freudians (and also perhaps inside) who have fulfilled these conditions is exceedingly small. This is the difficulty which such a society as the Medical Section of the British Psychological Society has to face, in deciding upon such a general discussion as that suggested by your correspondents.

The Medical Section is dominated, not by Freudians, but by a firm determination to probe the psychological secrets of mental disease to their depths, to base theory upon empirical evidence and not upon *a priori* arguments, and to be undeterred by mere *ex cathedra* statements, from whatever quarter. Discussion of Freudian doctrine among those adequately qualified to appreciate both the problem and the facts will always be welcomed in our society. Any other kind of controversy would be rather reminiscent of the fight between the elephant and the whale.

I should perhaps add that I am not a Freudian.—I am, etc.,

WILLIAM BROWN,  
President of the Medical Section, British  
Psychological Society.

London, W.1, Jan. 24th.

SIR,—In my previous letter (January 10th, p. 93) I said, on behalf of my colleagues, that we were "prepared at any time . . . to participate in any suitable conference, symposium, or discussion on psycho-analysis arranged by any medical or other scientific society." Sir Bryan Donkin, in his letter published in your issue of January 17th, replies that "the kind of discussion proposed by Dr. Ernest Jones . . . is very different from that which I suggested as desirable." The only alternative remaining would therefore appear to be that all those who have made a proper study of the subject, and have had personal experience of it—that is, psycho-analysis—should be excluded. Such a course might succeed in the aim of securing more complete unanimity, but it would surely be a very novel form of "scientific discussion."

I did not give it as my opinion that psycho-analysis had been frequently and extensively discussed "among well accredited medical and psychological authorities" (including, of course, both opponents and supporters of the method). I stated it as an easily ascertainable fact, and I am astonished that Sir Bryan Donkin should again assert the contrary in place of verifying the statement. He likewise refuses to accept my correction of his assertion that there was no discussion of the paper I read before the Royal Anthropological Institute, but merely multiplies his original misstatements by now saying: "This, however, took place on the occasion of an address by the President of the Institute and a following paper read by Dr. Jones, on the relation of anthropology and psycho-analysis, of which no criticism was made and to which no subsequent replies were admitted." The facts, which are easy to verify, are, on the contrary, that (1) my paper was not read on the occasion of the presidential address, but was the

only one read at that meeting; (2) there was extensive criticism made of it in the discussion that followed at the time; and (3) subsequent replies were admitted, for a sharp criticism of it was published in the following number of the official organ of the Institute.

In his previous letter, Sir Bryan Donkin said that neither of two particular attacks on psycho-analysis "has been replied to by any prominent advocate of this doctrine." Though I cited extensive replies that have been made twice over to them by prominent advocates of this doctrine, in just the place one would expect to find them, Sir Bryan Donkin again writes: "(1) can repeat confidently my statement concerning the non-existence of any adequate criticism by leading psycho-analysts of the two books." His first statement has been shown to be as misinformed as his other pronouncements in connexion with psycho-analysis, and I doubt if inserting the word "adequate" this time will help him much, for only those who have read the replies in question can judge of their adequacy.—I am, etc.,

London, W.1, Jan. 20th.

ERNEST JONES.

SIR,—I am one of those who would welcome a dispassionate discussion on the foundation principles of modern medical psychology. Psychologists are the very people who should be experts, not only in the theory of "emotion," but in the control, not repression, of their own emotions, and yet the subject suggested for discussion seems to excite anything but dispassionate treatment.

Obviously we are not going to make much progress if Freud is to be regarded as a medical Guy Fawkes, and we are to be invited to follow Drs. Wohlgenuth and McBride in helping to light the bonfire in which his effigy is to be consumed. Science is not to be advanced this way.

Perhaps the Royal Society of Medicine could promote a discussion on broad lines on this great subject. I would suggest that a preliminary private meeting of representative medical psychologists of different "schools" should be called together to devise the programme, and, without stifling discussion, it ought not to be beyond the wit of man to bring together those who, with the honour of the medical profession in view, would sanely and honestly state their views.—I am, etc.,

London, E.C.2, Jan. 16th.

CHARLES F. HANFORD.

#### WOMEN DOCTORS.

SIR,—It seems to me that your correspondents (January 24th, p. 192) present a very distorted view of the situation.

Taking Miss Ramsay's figures, not more than one woman to every twelve men has any reason to expect a resident hospital appointment on qualifying, and then only if she is as capable, or more so, than any one of the twelve men with whom she happens to be competing. Therein, I think, lies the answer to the question about the appointment of women doctors in hospitals, rather than "pure prejudice on the part of the male colleague." The lack of a hospital appointment is no reason why she should not go in for general or dispensary practice at home or abroad. Many of her male colleagues do so.

The public does need medical women in many spheres. It is up to such as these "45 out of 78 who have already held public appointments" to cast around and find where they are wanted, instead of seeking for a series of temporary posts.

To quote Dr. J. Walter Carr, C.B.E., for one instance, " . . . in India there are mission hospitals actually closed because no women doctors can be found to staff them." We need more of the stuff that the medical women of the generation just passing were made of—women willing to continue to carry out the responsibilities undertaken by the pioneers.—I am, etc.,

Birmingham, Jan. 25th.

FRANCES BRAID.

SIR,—Dr. Robinson's figures (January 17th, p. 140)—78 women applying for a resident medical officer's (hospital) appointment with £100 a year—are nothing compared with those given by a client of mine who, after repeated failures to secure any such hospital appointment, has

recently accepted an indoor assistantship in the Midlands, also with only £100 a year. She wrote me that she was selected out of 180 candidates! As to the permanent outlook for medical women Dr. Haunsay may be quite right. That there is at all events a temporary glut such startling figures conclusively prove.—I am, etc.,

Torquay, Jan. 24th.

HENRY BAZETT.

#### TESTS FOR DRUNKENNESS.

SIR,—We have read with interest and amusement the address of Sir James Purves-Stewart delivered on January 13th before the Society for the Study of Inebriety. At the same time we must confess to a certain feeling of disappointment; for we had hoped that the harassed divisional surgeon might perhaps derive from this lecture valuable assistance in the most thankless and difficult of all his tasks—something a little more helpful, for instance, than a half-hearted investigation to the performance of lumbar or cistern puncture! And there is one point on which we must at once join issue with Sir James Purves-Stewart—namely, his suggestion that “the police surgeon may be too open to suggestion.” We venture to submit that the police surgeon is very much less open to the charge of bias than is the medical man called in by the suspect for the express purpose of proving the latter’s sobriety. With a long experience of many police divisional surgeons we have no hesitation in saying that we have implicit confidence in their absolute impartiality. The divisional surgeon has nothing to gain by supporting the provisional diagnosis of the arresting police officer; in point of fact he very frequently reports on his man as being sober, and we are satisfied that when the divisional surgeon has any doubt as to the prisoner’s sobriety the prisoner gets the benefit of the doubt.

We also contend that a police surgeon attached to any of the big stations in Central London has an unrivalled experience in the recognition of inebriety in all its stages, and for ourselves we would prefer to rely on the opinion of such an experienced and impartial observer rather than on that of any other medical man, however eminent in his own particular line.

Again, we do not feel that Sir James Purves-Stewart has sufficiently emphasized the notorious fact that drunkenness may be a very transient phenomenon. We can most of us recall incidents in the course of bump suppers, or similar festivities, illustrative of this point—for example, the inco-ordination and dysarthria of the undergraduate at 10.30 p.m. who has pulled himself together and is conversing amicably (though perhaps with a slightly overdone solemnity) with the Dean at 11.15 p.m. The same sort of thing occurs not infrequently at the police station, if we substitute a distinguished consultant for the Dean of the bump supper days.—We are, etc.,

#### THE EFFECT OF LEAD ON RED BLOOD CELLS.

SIR,—Your note (January 17th, p. 131) on this subject cannot be passed without comment, because haematology has been so long neglected in England that it may be taken too seriously.

Experienced practitioners appreciate the fact that mild and early lead poisoning is often difficult to diagnose or to exclude. I had been diagnosing cases of plumbism in a village in County Durham for eighteen months before any medical man would accept the diagnosis. The worst case was an anaemic young woman, who had complete paralysis of arms and shoulder girdles, had to be spoon-fed by others, and was just able to totter across the kitchen of a small cottage. Two consultants in Newcastle diagnosed an unusual case of paralysis, gave a hopeless prognosis, and, as she was engaged, positively banned marriage. The man insisted on marrying the girl, even if it was only to nurse her till she died. Two years after I attended at her first confinement, when she was well, except that her hands were weak. At last I found a case with a blue line on the gums which

nobody could deny, and an investigation followed. The engineers of the Newcastle waterworks found that, in spite of their directions, houses had been erected here and there with a very excessive length of lead piping, and that my cases and suspected cases were entirely confined to these houses. The chief engineer was particularly interested in the woman because her home had the greatest length of lead piping in the village, and he pointed out to me how marriage removed her from this to her husband’s home, where the main pipe passed close to the door.

These cases happened many years ago when it was difficult to find evidence sufficient to warrant the diagnosis in such cases. About twenty years ago it began to be recognized that Grawitz and Hanel had proved the value of blood examination as an aid to diagnosis. In 1907, by treating various minor ailments with small doses of lead acetate, I satisfied myself by repeated examination of films that this was a most important advance. Then came Sir T. Oliver’s book on lead poisoning (1914), in which he declared that in the North of England blood examination had proved of no value. As my work was done in the North of England I may state that he and his experts were hopelessly wrong.

In commenting on the blood in plumbism, Dr. Cecil Price-Jones says, “basophilic stippling is sometimes observed, but not so frequently as was sometimes supposed.” In my last fourteen cases it was not once absent. Besides, it is futile to single out punctate basophilia. Ignoring punctation altogether, those who persistently wash it out should look for polychromasia, megalocytosis, Jolly bodies, Cabot rings, and erythroblasts; these are less easily banished from a film, and accompanied basophilia in my fourteen cases. Even those who find basophilia in the majority of healthy persons might find a safeguard in so doing. It would probably puzzle them to be told that for years I looked out for leucoblasts in these films and found them last year for the first time in a case of lead poisoning.

I had the privilege of stating my experience in your pages<sup>1</sup> and explaining my technique,<sup>2</sup> and would conclude with these words: In plumbism, long before muscle, nerve, or intestinal symptoms, the metal acts on the marrow, and the blood promptly shows definite, constant, and conspicuous changes. Consequently there is no reason why industrial absorption should ever advance to lead poisoning.—I am, etc.,

Ealing, W.13, Jan. 18th.

ROBERT CHAIN, M.D.

#### ACIDOSIS AND ACETONAEMIA IN RELATION TO SEA-SICKNESS.

SIR,—The interesting contribution by Surgeon Sydney Jones, of R.M.S. *Aquitania*, in your issue of January 17th under the above heading encourages me to submit some observations I have made on this subject during the past ten years. The relation of acetonaemia to sea-sickness and the allied conditions—air-sickness, train- and car-sickness—was first brought to my notice in 1915, when, as a naval surgeon attached to the airship subsection of the (then) R.N.A.S., I was called upon to examine officers and ratings from the special point of view of fitness for flying. Acidosis was regarded as of considerable importance; it was always suspected and the urine tested for acetone if the applicant was unable to hold his breath comfortably for more than thirty seconds. This simple test proved to be almost infallible. Should the officer or rating have had previous experience in flying a history of air-sickness was present in all cases of positive acidosis. By “air-sickness” a condition identical with sea-sickness is inferred, due to the motion of the airship, scaplane, or kite balloon, and not in any way due to high altitudes, this point being clearly stressed by the fact that air-sickness was always worse in kite balloons, working at a lower altitude, than in any other form of aircraft. During two years with the R.N.A.S. the close correlation between air-sickness and acidosis appeared to me to be an established fact. Part of 1917 and 1918 spent in the Eastern Mediterranean in surface craft did not give many opportunities for pursuing this investigation, but a number of outstanding cases of

<sup>1</sup> BRITISH MEDICAL JOURNAL, 1923, i, 103. <sup>2</sup> *Ibid.*, 1924, ii, 728.

intractable sea-sickness, described by the men themselves as "absolutely paralytic," bore out Surgeon Sydney Jones's recent observation that 99 per cent. of cases of vomiting at sea, not due to an obvious organic lesion, are accompanied by increased acidity and acetonaemia. Since resuming civil practice after the war, acetonaemia in children has claimed my attention, and some of the following observations bearing on the subject were published by me in *St. Bartholomew's Hospital Journal*, March, 1924, under the title "Some practical points in the diagnosis and treatment of acetonaemia in children."

A simple bedside test for acetone is of first importance, and can easily be performed by using a small endolytic (capillary) tube containing sodium nitro-prusside and ammonium chloride (put up by Fletcher and Fletcher, of Holloway, N.). One large drop of urine is taken on a sheet of notepaper, and saturated with a common washing soda crystal the size of a pea. This saturated urine is allowed to run up the tube by capillary attraction, the reagent having been shaken to the lower end; if acetone is present in the urine in quantity a petunia colour develops in about thirty seconds, and even when only small amounts are present a rosy or amethyst flush is noticeable in about a minute or two. When acetone is absent the powder dissolves with nothing more than a pale straw coloration, which does not develop further. A routine examination for acetone in the urine of all children coming under notice reveals the fact that it is found in more cases than one would suspect. All cases of recurrent bilious attacks, tonsillitis, pneumonia, and practically all febrile attacks only account for about 50 per cent.; in the remaining 50 per cent. acetone has been detected as a result of routine examination where it would not have been otherwise suspected. These children came under observation because they were out of sorts, had bad appetites, were bad-tempered, or did not gain weight; several recent cases evidenced disordered action of the heart and nothing else.

In treatment, unlike Surgeon Sydney Jones, I hold a brief for glucose. Cases of cyclic vomiting do not appear to tolerate alkalis by the mouth during the attack, but take glucose readily, and retain it when everything else is returned. A heaped-up teaspoonful of glucose in half a taceup of cold water, repeated every two hours until four or five doses have been taken, has produced in cases of urgent acetonaemia in children 5 or 6 years old the same wonderful improvement described by Surgeon Jones as resulting after the treatment of his distressing cases of sea-sickness with high-rectal injections of sodium citrate. Feeding with glucose appears to me to give relief in practically all cases, and if no symptoms are present it has the effect of clearing up the acetone in the urine. Concerning Surgeon Jones's final remark on the advisability of correcting hyperacidity before embarking, I have recently carried out very successful prophylactic treatment on these lines among juvenile patients who suffer from train- and ear-sickness associated with acetonaemia, on returning to boarding school after the holidays. A round of parties and dances, with concomitant indiscretions in diet, had produced in these cases a lively acetonaemia, but this was controlled by one day of meagre diet and several feeds of glucose at the end of the holidays, the long train or car runs being subsequently undertaken without any inconvenience. The same prophylactic measures do not appear to be so necessary on returning home at the end of term, as the healthy and simple diet of the average preparatory and public school does not seem to be very productive of acetonaemia.—I am, etc.,

Midhurst, Sussex, Jan. 21st.

B.S. Lond.

#### ASSETS OF THE I.M.S.

SIR,—The Indian Medical Service, "for official reasons," is moribund. Hence it is worth while ascertaining what are its assets. The formation of the Clive Fund in 1770, in which both medical and combatant officers had rights, was followed at successive periods by the institution by the Medical Service of separate funds in the respective Presidencies. In 1867 the Madras Medical Fund was inaugurated

on the basis of an assurance society; by 1829 subscriptions by official orders were compulsory. The ends to be met were the provision of pensions for widows and children, passages for officers on sick leave, and of annuities for senior officers on retirement. The latter object was not only of value to individuals but to the whole service, in that an inducement was offered for early vacation of appointments by seniors. Lieut.-Colonel D. G. Crawford, I.M.S., in his work *A History of the Indian Medical Service, 1600-1913* (vol. i, p. 482) thus describes the fate of this fund:

"The assets, liabilities, and management of this Fund were transferred to Government from 1st April, 1870, by Despatch No. 101 M. of 9th December, 1869; and after that date no new members were enrolled. In 1880 it was decided that it was not desirable to offer to members a refund of their subscriptions. For many years annuities from this Fund continued to be granted yearly. All members have long since retired, but some are yet living who still draw their annuities."

It will be noted that transfer to the Government of India of assets and liabilities of the fund was effected by official orders. This method usually leaves but a Hobson's choice to those addressed.

Having regard to the existence of organized military and civil departments dealing with finance, it is unlikely the extra strain caused by the transfer of funds could have rendered necessary other than trivial addition to their personnel and consequent cost of management. Tradition holds that the capital transferred to Government in 1870 was a very substantial sum, whilst, as the above extract shows, further increments of liabilities were prevented by the Government directing that no new members be enrolled. In 1880 it decided that it was "not desirable" (1) to refund subscriptions to former members, thus affording an unexplained departure to its mode of dealing with the Bengal Medical Fund, where repayment was made to subscribers minus 10 p.c. (sic).

Obviously, at the present date, demands upon the fund must have vastly decreased, whilst interest on capital should have accumulated. Unless, therefore, documents dealing with the transfer gave the Government of India, with the consent of the subscribers, absolute right to the capital coupled with the power exercised by it to refuse further liabilities by enrolment of new members, it follows that it is in possession of funds as trustee beyond the requirements of liabilities. It seems to me, therefore, well within the functions of the British Medical Association to ascertain from the Secretary of State for India whether this view of the matter can be maintained, or whether the transfer was ordered on philanthropic principles. Should the latter suggestion be untenable, there are doubtless immediate heirs of subscribers who would not object to a share of the fund capital, whilst there are purposes, scientific and charitable, which might be benefited by gifts in *memoriam* of the I.M.S.—I am, etc.,

Hendon, N.W.4, Jan. 23rd.

W. G. KING,  
Colonel I.M.S. (ret.).

#### WHAT IS THE DEFINITION OF "ATTRIBUTABLE" IN WAR INJURIES?

SIR,—I desire to obtain opinions upon the following case. A soldier in September, 1918, when on duty, was bitten in the neck by a horse. The wound healed with a "lump" in the scar and impaired movement of neck and arm. He was demobilized in March, 1919, with a scar and lump; he worked intermittently, the lump getting larger, but did not consult a medical man until February, 1923, when the tumour involved too much for operation. Radium tubes did no good, and the man died, after repeated haemorrhages, in 1924.

The local Pensions Board turned the widow down on the ground that the cause of death was not attributable to the wound; and on appeal, though the chairman admitted the sequence of the disease and wound, it was ruled that too much time had elapsed from the receipt of the injury to the death, and so it could not be attributable.

I therefore should be glad of opinion on the subject.—I am, etc.,

Folkestone, Jan. 18th.

P. BROOME GILES,  
Colonel A.M.S. (Ret.).

## Obituary.

SIR JAMES MACKENZIE, M.D., F.R.C.P., F.R.S.,  
Director of the Institute for Clinical Research, St. Andrews.

(With Portrait on Special Plate.)

SIR JAMES MACKENZIE died at his residence in London on the morning of January 26th. He had been suffering from angina pectoris for some time, and about a year ago decided not to spend another winter in St. Andrews, where he had gone to live after leaving London in 1918. At St. Andrews he had a delightful house and garden, and there he founded the Institute for Clinical Research, to which he gave a great part of every day while his health permitted. With him English medicine loses one of its great names. For over a quarter of a century he was in general practice in Burnley, and it was during those years that he began and carried far forward the investigations which were to revolutionize cardiology. He attained a position of world-wide eminence as a research worker and clinical investigator in what is admittedly a difficult subject. His success was due to a buoyant temperament which, coupled with untiring industry, enabled him to get through an immense amount of work; to a well founded belief in his own capacity to observe and reason correctly; and to an innate mental fearlessness and integrity which compelled him to rest his doctrine on facts rather than on authority.

He was born in Scone, the ancient coronation place of the Scottish kings, on April 12th, 1853; he was educated at Perth Academy and at the University of Edinburgh, where he graduated in medicine in 1878, and received the degree of Doctor of Medicine in 1882. After a term spent as house-physician in the Edinburgh Royal Infirmary immediately following graduation, he began practice in Burnley in Lancashire, and remained there for twenty-eight years. It was during his residence in that town, and while engaged in all the activities of a busy general practitioner, and with a hospital appointment, that he carried out the investigations which led to the introduction of the polygraph as a means of studying the various irregularities of the pulse. Perhaps during no part of his life is his character as a painstaking, persevering investigator better brought out. He says in the preface to one of his publications that amid the distractions of his daily work he has "seldom been able to give an uninterrupted hour's study to the subject." There is no doubt, on the other hand, that much of his research could not have been undertaken otherwise than in general practice, for many of his conclusions were arrived at after following the course of disease in individual patients over many years.

Mackenzie early turned his attention to the investigation of the interpretation of the pulse, and to the elucidation of the various cardiac rhythms. We find him in 1892 in the *Medical Chronicle* publishing a paper on "The symptoms associated with visceral disease," and two years later, to the *Journal of Pathology and Bacteriology*, a paper on "The venous and liver pulses and the arhythmic contraction of the cardiac cavities"; but it was in 1902, when his book on *The Study of the Pulse* appeared, that Mackenzie became definitely recognized as one who had produced a work as likely to revolutionize our ideas of the pulse, and we find this book translated into German, in which country his work was already attracting attention.

In 1907 he settled in London and quickly took his place as one of the foremost consultants in diseases of the heart. He was appointed physician to the Mount Vernon Hospital for Diseases of the Chest, and some years later (about 1913) became physician in charge of the cardiac department at the London Hospital.

In 1908 there appeared his *magnum opus* on *Diseases of the Heart*, which, in the course of five years, went through three editions, and was translated into German, French, and Italian. When war broke out his wards were utilized for military purposes, and he had perforce to give up his regular teaching, though he continued his consulting practice in London till 1918. During his residence in London

he was the recipient of many honours. In 1911 he delivered the Oliver-Sharpey Lectures and also the Schorstein Lectures—in the former dealing with heart failure and in the latter with auricular fibrillation. In 1914 he was appointed first George Alexander Gibson Memorial Lecturer at the Royal College of Physicians, Edinburgh, and in 1915 he was elected Fellow of the Royal Society for his researches into the heart in health and disease. In the same year he received the honour of knighthood from His Majesty, and a few years afterwards was appointed honorary consulting physician to the King in Scotland. During this period he also produced his shorter work on the *Principles and Diagnosis of Treatment in Heart Affections* and in 1909 a book on *Symptoms and their Interpretation*, which passed through four editions and was translated into four European languages.

Following his resignation from the London Hospital his work took on a new aspect, and the publication in 1919 of his book on *The Future of Medicine* raised a considerable amount of discussion. His aim was to encourage research in the beginnings of disease, and with this object in view the St. Andrews Institute for Clinical Research was founded, and to it Sir James Mackenzie devoted the remaining years of his life.

Many of his most important contributions to periodical medical literature, both during his residence in Burnley and afterwards, were published in this *JOURNAL*; the most recent were "A new outlook in cardiology," a long paper which ran through three numbers and dealt in particular with the sino-auricular node, the auriculo-ventricular node, auricular flutter, and the cause of heart failure; a "Preliminary inquiry into the nature of the cell impulse"; and his last contribution, "A plea for clinical physiology," all published during 1924. In addition to the papers in this and other medical journals he had published in recent years two books—one on *Heart Disease and Pregnancy*, and the other, the most important of his later works, on *Angina Pectoris*, which was the result of his investigations into this subject from the time of his early days in Burnley.

Born in Scotland, of Scottish parents, Mackenzie never lost the dogged determination that is said—not without truth—to be characteristic of that nation. Endowed with an inherent inclination to surmount difficulties, he manifested that form of genius which is defined as being "the infinite capacity for taking pains," but he was also possessed of vision and was not content to confine himself to the broad road. In his later years he concentrated his energy on stirring up a righteous discontent in the profession with things as they are, and, adopting the prophetic mantle, aimed at showing it a more excellent way.

The magnitude of the work he did in connexion with disease of the heart has been recognized all over the globe. He was early impressed with the inability to interpret the different irregularities of the pulse, and out of the chaos of the nineteenth century he evolved the order of the twentieth. Had he done nothing more than isolate the heart with auricular fibrillation from other conditions, and demonstrate its relation to digitalis therapy, he would have placed the profession under a lasting debt of gratitude. His work with the polygraph may be said to have revolutionized our knowledge of the cardiac mechanism and put the diagnosis and treatment of certain diseases of the heart on a logical basis, while it laid the foundation upon which most of the more recent work has been done. His views on cardiac failure are now so generally accepted that it is already difficult to realize that he put a new complexion on this aspect of the subject, and if some may have thought that he took an extreme position it must be remembered that it required strong dogmatic teaching to arouse a self-satisfied profession.

Throughout the course of his research on heart disease he was constantly met with difficulties from his inability to interpret many simple symptoms, and he was thus led into bypaths which he has illuminated in his earnest endeavour to seek out the truth. Perhaps nowhere is his thoroughness and his determination to get first-hand information better illustrated than when he describes in his book *Symptoms and their Interpretation* an operation at which he was the

*Macdonald*

surgeon: "I had occasion to resect a small portion of the small intestine in a conscious subject, for umbilical fistula, whose abdominal cavity I laid open. He refused to take an anaesthetic, and no analgesic, local or general, was administered"; and then follow the results of his observation, illustrating his views on the reflex character of visceral pain. He considered that the taking of surgery out of the hands of the general practitioner was a great loss to medicine, and he maintained that if practitioners could not themselves perform an operation on a patient they should at least be present to find out the explanation of the symptoms.

He long held the view that medicine was taught in the wrong order, and that the simpler and commoner diseases should be demonstrated by the out-patient department, while a junior physician would be quite competent to teach in the wards on the fully developed diseases. When he retired from consulting practice in London he had already prepared his plans for an Institute of Clinical Research, and in St. Andrews he found an ideal centre, with a comparatively stationary resident population, for putting into practice his views regarding the study of the beginnings of disease. He realized that it would be many years before the Institute could prove its real value, but he hoped to have the opportunity of training others in the method he considered best adapted for the purpose in view. It is yet too soon to estimate the full results of this scheme, but under his directorship many valuable contributions to clinical medicine have already appeared in its published reports, while the practitioners in St. Andrews who are on the staff of the Institute acknowledge the very great assistance it has been to them in their practices, and the inspiration and interest in their work which contact with the "Chief" has engendered. He had the power of inspiring enthusiasm among his co-workers, and he never lost an opportunity of preaching his principles to any visitors who came to the Institute. In his presence one could not fail to be affected by the magnetism of his personality. When carried away with his own views, whether in conversation or in writing, he was apt to leave the impression that other lines of investigation than those adopted by him were useless, and in this way his diatribes against stethoscopes, electro-cardiographs, valvular murmurs, and morbid anatomy were apt to be misleading to those who did not understand him. For all of these things, however, he found a useful place in his own writings, and his aim was to prevent others from giving them an undue prominence in their medical work.

He was probably not at his best with a large audience. The attention required for careful dictation was liable to curb the flow of his thoughts, and he was apt to drop into a more colloquial and forceful manner of address. He was at his best with a few listeners, and he could always display an earnestness and sincerity which never failed to impress. Kindly in disposition and always approachable, though sometimes almost brusque in manner, he never lost an opportunity of trying to inculcate his views on the many medical men who visited him from all parts of the world. Though it may be said that he lived for his work, he found time to have a daily round of golf until latterly he found the strain too much. His health had been failing for some time, but even when his attacks of pain were becoming more frequent and more acute he still found time to devote to his work. Like not a few men who have risen to eminence in the medical world, he was cut off by an affection of that organ the functions of which he had done so much to elucidate.

In 1887 he married the daughter of Dr. George Jackson of Boston: two daughters were born to them. To Lady Mackenzie, his devoted wife, and to her surviving daughter, from both of whom he received untiring encouragement and help in his happy home life, the sympathy of the profession and their large circle of friends will go out in their grievous loss. His brother is Sir William Warrender Mackenzie, K.C., K.B.E., one of the editors of *Lancet*. The portrait with which this notice is illustrated is from a photograph taken at the Institute for Clinical Research, St. Andrews, by Mr. Smith. We are indebted for it to Professor Waterston.

#### TRIBUTE BY SIR THOMAS LEWIS.

We are indebted to Sir Thomas Lewis for the following tribute to Sir James Mackenzie's character and work: It was in 1908, and shortly after he migrated to London from his old home and practice at Burnley, that I first came to know Mackenzie personally. While it was never my privilege to work under his supervision, yet he extended to me, though many years his junior, a friendship which soon became intimate and highly prized. I found in him during those years before the war, when we were in almost daily and personal communication, a man wholeheartedly devoted to the search for knowledge of disease, and eager, most eager, to impart his spirit and conceptions. He was an exceptionally vigorous and strong personality, intolerant in criticism, rich in personal experience, combative in argument, but open nevertheless to conviction on all questions without reserve. He saw, as few or none of his day saw, where clinical knowledge ends and ignorance begins, and never hesitated to define the limits of his knowledge; I frequently heard the words, "I don't know." To him diagnosis, the affixing of a contemporary label, gave little satisfaction; his patient still contained his problem or his problems. Mackenzie's mind could not rest on the known, but turned incessantly, at each and every hour of the day, to the unknown, and in perceiving and defining the unknown he displayed a masterly power. To know Mackenzie intimately was to imbibe independently of thought; none could go to him seriously to discuss and survive the growing shocks of that first interview, return without a gift of stimulation and stimulus. For he possessed the As a man he was hard-headed and warm-hearted, quick in temper and in sentiment, genial and hospitable, possessed of an invigorating blunt humour. Schooled by long experience in the sensibilities, reservations, obstinacies, and frailties of patients, he was an astute and shrewd physician, who rarely failed to inspire an unlimited and merited confidence.

This briefly of his practical work as I knew it; as a bedside investigator he ranks, in my judgement, as the first of his time; he has gone from us to hold a place in the history of British medicine by the side of Sydenham, Stokes, Graves, Addison, and Bright, and he will live in memory as not the least of such men. To describe the solid work accomplished by him in his long, arduous, but always enthusiastic struggle for "the light," to attempt to weigh its detail and to assess its breadth, not in one but in its many phases, fully and truthfully, cannot be done briefly; to summarize that which most of his contemporaries in large part know—I think, belittle the greatness of his achievement. To the end of a long and painful illness, when the hand of that malady which John Hunter also suffered, and into which none had a clearer insight than Mackenzie, heavily upon him, his mind retained all its former alertness, searching his own bodily symptoms, and not unsuccessfully, for some further clue to their meaning; this last contribution was to him inevitable, being but a natural epilogue to the drama of a full and rich life.

#### A TRIBUTE FROM ST. ANDREWS.

In the deep sense of recent personal loss it is not easy for his St. Andrews colleagues to pay an adequate tribute to the memory of Sir James Mackenzie, and it is possible only briefly to mention some aspects of his work and his influence there. Sir James Mackenzie's work culminated in his foundation of the Institute for Clinical Research at St. Andrews. The reasons which induced him to establish the Institute there and the special line of research which he desired the Institute to represent have been fully expounded by himself in various papers and in the reports of the Institute. As a clinical investigator his work began with the observations which he made while in practice at Burnley. His busy consulting and hospital practice in London added to the wealth of his experience, but it was in his work at the St. Andrews Institute that he summed up and put forth

the considered conclusions drawn from the clinical observations made during the course of his life's work.

The conception of an Institute devoted to clinical investigation was the outcome of his pioneer work as an investigator while a general practitioner. He formulated the fundamental truth that medicine is a special branch of science dealing with a special group of phenomena to which the clinical investigator must apply the methods specially suitable for his purpose. Other sciences have their contribution to make to medicine, but they are to be regarded as ancillary, and not replacing the proper methods of clinical investigation into the phenomena of ill health and disease which afford the material for study. Among other things, it was essential, in his view, to employ the opportunities the general practitioner alone possesses of watching the "life-history" of ill health in patients over a long course of years.

St. Andrews was known to him, was a place of convenient size, and seemed in other respects suitable for launching his great enterprise. After paying some visits to it he decided to give up his appointments and his work in London and to devote his energy and ability to this new field.

What it meant to leave London and his work there is not easily estimated. The London Hospital authorities had given him every facility for special hospital work. His position had been recognized as a great consultant, clinician, and teacher. He deeply appreciated the facilities which had been afforded him, both at the London Hospital and at the Mount Vernon Hospital, Hampstead. But he realized that he could not in London carry on the work which he felt was fundamentally necessary for the advance of medicine, and after full consideration he decided to leave London and to devote himself to founding a research institute.

He came to St. Andrews unknown to all but a few of his medical colleagues, and began at the Cottage Hospital a series of clinics in the out-patient department, to which he soon attracted all the practitioners. These clinics rapidly produced the desired effect and aroused in his audience the desire to co-operate in the work which he showed them was waiting to be done. With the assistance of generous friends who were deeply interested in his ideas, and with his own financial help, a suitable building was secured and fitted up, and the definite work of the Institute was begun. At a later stage, as the usefulness and value of the work became realized, additional help was given by the Carnegie Trust and by the Medical Research Council.

Of the work which has been accomplished at the Institute this is not the occasion to write at length, nor is it possible as yet fully to estimate the significance and the far-reaching results of this pioneer movement in medicine. It has already had an influence far wider than a merely local one, and medical thought and medical practice in many countries of the world have received from it direction and guidance. The recent award to him of the Mickle Fellowship of the University of Toronto is an illustration of the wide recognition given to his work in St. Andrews.

For three years he devoted his whole time and thought to the work of the Institute and to the training of those who worked with him there, and then, satisfied that he had laid down the lines for their work, he gradually withdrew himself from active direction, and gave to the members of the Institute the opportunity of carrying on the work by themselves. At a still later stage his health began to fail, and he decided to winter in a milder climate, but to the very last the welfare of the Institute was foremost in his interests and thought.

It is not easy for his colleagues to realize fully the extent of the loss they have sustained by his sudden death. His vivid personality and the vigour of his mind had made a deep impression upon them and the stimulus of coming into contact with him in discussion and debate was of incalculable benefit to them all. They realized the greatness of his genius and his extraordinary insight into medicine, and they had come to look upon him, not only with respect and admiration, but with the most sincere affection.

Great as was the influence of his personality his colleagues

feel that the value of his work did not depend upon that element, and will not end with his death. Not only is his work upon the heart, but in the wider field of general medicine, his observations and the principles which he has deduced from them are of permanent and abiding value.

SIDNEY BARWISE, M.D., B.Sc., D.P.H.,  
Medical Officer of Health for the County of Derby.

The death of Dr. Sidney Barwise on January 24th came as a great shock to his large circle of friends and to the public health branch of the profession generally. Although for some little time his health was giving cause for anxiety, his mind still retained its remarkable activity, and his energies seemed unabated in devising schemes for the benefit of humanity. His position amongst medical officers was in some respects unique, and his loss will be very real.

Sidney Barwise studied medicine at Queen's College, Birmingham, and obtained the L.S.A. in 1884 and the M.R.C.S. diploma in 1885. Two years later he graduated M.B.Lond. and proceeded M.D. (in State medicine) in 1893. He obtained the B.Sc. of Birmingham University in 1904. He had commenced his public health career in Blackburn in the year 1889. Although he only held the post of medical officer of health for that town for two years, he organized its sanitary administration on sound lines and conducted important investigations into two pressing problems—the smoke nuisance and the health of cotton operatives. Although the foundations of his reputation as a public health worker were laid whilst in Blackburn, it was as the medical officer for the county of Derby that his life's work was done. During the earlier years, when the powers and duties of county councils were much more restricted than they now are, his energies were more particularly directed to the provision of isolation hospitals for infectious disease and the prevention of river pollution. In both these branches he did pioneer work.

A colleague in the public health service writes: Barwise's real opportunity occurred with the extension of the duties of county councils to personal preventive medicine under the schemes of medical inspection of school children, maternity and child welfare, prevention and treatment of tuberculosis and venereal diseases, and the Midwives Act. His work under these schemes has not only proved to be of great value to his county, but has often been a real inspiration to his fellow workers in other parts of the country. His scheme for the dental treatment of school children was perhaps the most complete of any county scheme. It embodied the controversial procedure of employing dental dressers, but in his opinion this was the only method at the present time by which the great mass of school children of the country could get efficient treatment. He may have been right or wrong, but it was characteristic of him that, having come to this conclusion, he pursued his course in face of great opposition, buoyed up with the intense conviction that he was acting in the best interests of humanity. Barwise had the public health "sense" very strongly developed, and his fertile mind was almost continually engaged on schemes, many practicable, some impracticable, for the betterment of the people. As showing that his interests were not entirely confined to his work, it may be mentioned that a letter written in 1912 forecasting the war and the details of invasion of Belgium and France proved remarkably correct in detail and showed that he was a student of contemporary history. Notwithstanding his long and valuable service, one cannot help feeling that by his death a career has been cut short which still had much promise. Dr. Barwise leaves a widow and two children.

Another colleague writes: To any member of the public health service who was privileged to know Dr. Barwise his sudden death will come as a great shock and cause real grief. His infectious enthusiasm, his keenness to acquire knowledge, his energy, which seemed never to flag, and his generosity and kindness, will always be treasured memories to his staff. During the long period he was county medical officer for Derbyshire there was an unceasing

output of work, each of his annual reports, always so stimulating and interesting, showing some fresh achievement. And now that he has laid down the reins there remains as a record a public health department which must be a great source of pride to the Derbyshire County Council and the envy of others.

**JOHN FRASER, M.B., C.M., F.R.C.P.Ed., F.R.S.Ed.,**  
Retired Commissioner, General Board of Control for Scotland.

THE death of Dr. John Fraser at his residence in Edinburgh on January 18th removes a notable figure in Scottish lunacy affairs. Dr. Fraser, who was in his 80th year, recently rendered him unconscious, and, although he lingered on for some days, the shock at his advanced age proved fatal.

John Fraser was born at Thornhill, Dumfriesshire, where his early years were spent. He studied medicine at Edinburgh University, where he had a distinguished record, gaining nine medals in his medical classes, and he graduated there as M.B., C.M., with first class honours, in 1870. After qualifying, he held resident appointments in Edinburgh Royal Infirmary, and thereafter his attention was directed towards the study of mental diseases. In 1871 he was appointed assistant medical officer at Fife District Asylum, Cupar, and a few years later he succeeded the late Sir John Batty Tuke as medical superintendent. The ties of friendship between those two distinguished alienists were later drawn closer by the marriage of John Fraser to Batty Tuke's daughter. In 1877 Fraser was appointed a Deputy Commissioner in Lunacy. As a Deputy Commissioner Fraser's duties were mainly concerned with the insane living under private care, and into this work he entered more thoroughly the system of boarding out patients in private dwellings under suitable guardianship, a scheme which had been initiated by his predecessor, Sir Arthur Mitchell. His energy and enthusiasm soon gained the entire confidence of inspectors of poor and other officials, and animated many of them with his conviction as to the advantage of such a system both to the ratepayer and as a measure of justice to the many insane who, under slight supervision, are capable of enjoying the liberties and pleasures of a natural home life. The system of boarding out suitable cases became generally adopted throughout Scotland, and it has continued to be a marked feature of Scottish lunacy administration. In 1895 Fraser was appointed Commissioner in Lunacy, and in his new capacity he gained the confidence and esteem of his superintendents and other asylum officials. The superintendents regarded them less as an official critic than as a friendly and outspoken adviser whose mature experience and knowledge were always at their service—one who sympathized with them in their difficulties, and was always ready to do all in his power to assist them both with kindly counsel and active support.

Fraser's official connexion with lunacy—extending over thirty-nine years—covered a period of general progress in every direction in the treatment of the insane. There was no method of treatment of recognized merit which escaped his notice or failed to receive his warm approval and support; once convinced that it was for the benefit of the insane he did his utmost to influence others to adopt it. He was thus a real and active force in promoting the most progressive views. His name is bound up with the history of the treatment of the insane in Scotland, and his period

of office as a Commissioner was a most fruitful one and left an indelible mark on the internal administration of asylums, and through his efforts he greatly assisted to improve the conditions for patients in the Scottish asylums. Among the advances initiated during his time may be mentioned particularly the hospitalization of the insane, improved and more efficient systems of nursing, with both by day and by night. He was a strong advocate of all non-restraint methods of treatment, and also of the nursing of male patients by female nurses, which now characterize the administration of Scottish mental hospitals. He was largely instrumental in having precautions against fire perfected in all asylums, and in having efficient means provided for the safety of the patients.

His kindly manner and cheery optimism earned for him the respect of both patients and staff as a genuinely sympathetic visiting Commissioner to whom appeals were never made in vain. His kindly words of advice comforted many and helped smooth difficulties and dispel misunderstandings, the patients feeling that in him they had a real friend, who too a genuine interest in their welfare. As a Government official and public servant he was highly respected, and he worthily maintained the traditions of his office. Dr. Fraser, on his retirement from the General Board of Control under the age limit in 1910, was publicly presented by his numerous friends and admirers with his portrait painted by Mr. Fiddes Watt, R.S.A. Since then he had devoted his time and energies to charitable organizations, more particularly the Society for the Prevention of Cruelty to Children, in which he was keenly interested. He was a director of the Royal Scottish National Institution at Larbert for the care of the feeble-minded. He was predeceased by his wife in 1917, and he is survived by three sons, one of whom is an ear and throat specialist in Edinburgh, and two daughters. A memorial service was held in St. Cuthbert's Parish Church, Edinburgh, on January 21st, at which representatives from various public bodies were present, with many personal friends. The interment was in the Dean Cemetery, Edinburgh.

DR. JOHN FRASER.

We regret to announce the death of Dr. GEORGE COOKE ATTFIELD, on January 16th, within a few days of his 99th birthday. Dr. Attfield was born at Bath on January 27th, 1826, and was educated at St. Bartholomew's Hospital; he obtained the diploma of M.R.C.S. Eng. in 1850. For some years he was medical officer of Millbank Prison, and he subsequently became chief medical officer of prisons in Western Australia, where he remained until the demolition of the convict settlement in 1879. He then returned to England and went to live at Hove. From his early youth he was a keen sportsman, and was especially distinguished as a cricketer. He played at one time in Somerset XI, and it is said that when in Australia he was invited to join an All-England team touring in that country, but was unable to accept. He continued to take the keenest interest in county cricket until his death, and was also well known as a billiard player. Dr. Attfield could remember the epidemic of cholera in London in 1842-3, and during the London bread riots of 1848 he served as a special constable. At the time of his death he was believed to be the oldest medical practitioner in England.

At the death of Dr. OWEN BOWEN, which took place on January 19th, Liverpool loses one of its best known practitioners in the North End. Dr. Bowen had been far from well during the past two years, but with characteristic fortitude continued to practise till within a few weeks of his death. He qualified in 1876, taking the usual qualifications

The diploma of the Society has been granted to Messrs. A. J. Dowek, L. Freeman, E. F. Hottinger, E. J. P. McDowell, A. J. Moody, C. C. Taffs, and C. W. Warne.

Dr. ARTHUR G. CHEYNE IRVINE died at Wellington College, Berks, on January 20th after a long illness contracted during war service as a temporary captain R.A.M.C. Born at Coleraine, Ireland, in 1864, he was educated at King Edward's Grammar School, Birmingham, whence he passed to Queen's College, Birmingham, to study medicine, obtaining the diplomas of M.R.C.S.Eng., L.R.C.P.Lond. in 1890. After a year as assistant house-surgeon to the West Bromwich Hospital he set up a practice at Selly Oak, Birmingham, where his clinical acumen, keenness, and sympathy soon won the esteem of a large number of patients and fellow practitioners. For some years he acted as general secretary to the Birmingham and District General Practitioners' Union. In 1914 he was actively engaged in examining recruits, and in 1915 received a commission in the R.A.M.C., serving at Salisbury Plain, and then at the Command Depot, Sutton Coldfield. He was promoted to captain in 1916, but was invalided out of the service in July, 1917, and with great fortitude and patience lived through eight years of ill health in retirement, leaving a widow and one daughter. Fond of reading, and a really good chess player, representing his county in tournaments, Dr. Irvine bravely adapted himself to the limitations imposed by his ill health, and those who knew him were filled with admiration at his courage and feel that his death is a very real loss to the medical profession.

## The Services.

## DEATHS IN THE SERVICES.

Colonel Robert James Copeland, Army Medical Staff (ret.), died in a nursing home at St. Leonards on January 11th, aged 62. He was the son of the late Major Copeland, of the Indian army. He was educated at Edinburgh, where he graduated M.B. and C.M. in 1886, and entered the army as surgeon on July 27th, 1887. He became lieutenant-colonel on January 30th, 1912, was on temporary half-pay on account of ill health from March 10th to September 10th, 1912, and was promoted to colonel in the big war promotion list of March 1st, 1915. He served throughout the South African war of 1899-1902, when he took part in the relief of Kimberley; in operations in the Free State, including the actions at Paardeberg, Poplar Grove, Dreifontein, Karre Siding, and Pretoria, Diamond Hill, and Belfast; and in Cape Colony, in the clasp and the Queen's medal with six clasps and the King's medal with two clasps. He also served throughout the recent great war as A.D.M.S. of a division, and in command of a general hospital. He retired on August 10th, 1919.

Lieut.-Colonel Delaware Lewis Irvine, R.A.M.C. (ret.), died on January 14th, aged 71, in Westminster Hospital, of injuries caused by being knocked down by a motor lorry when crossing Whitehall on January 7th. He was born at Jesmond, Newcastle, and entered the army as surgeon on July 31st, 1880, became lieutenant-colonel after twenty years' service, and retired on March 28th, 1908. After retirement he was employed from 1909 to 1913 as staff officer to the A.M.O., North Midland Division, Territorial Force. He served in the Sudan expedition of 1884-85, in the Nile campaign, medal with two clasps and the action of Kirbekan, and received the South African war in 1899-1900, when he took part in the actions at Paardeberg, Poplar Grove, and Dreifontein; in those in the Transvaal, with the actions near Johannesburg, Pretoria, and Diamond Hill; and in Cape Colony, in the action at Collesberg; and received the Queen's medal with five clasps.

Major Arthur George Edward Newland, Madras Medical Service (ret.), died in Edinburgh on December 28th, 1924, aged 67. He was the son of the late Charles Edward Newland, schoolmaster, Bangalore. After completing his medical course he served for a time as a civil assistant surgeon in the Madras Medical College, 1879-80. Coming home, he took the L.R.C.P. and S.E.D. in 1880, and entered the I.M.S. as surgeon on April 2nd, 1881, becoming major after twelve years' service, and retiring on August 1st, 1899. He served at Suakin in the Sudan campaign of 1885, in Burma in 1886-89, receiving the frontier medal with a clasp; in the Manipur campaign of 1891 (clasp); and again in Burma from 1891 to 1896, taking part in operations in the Chin Hills and on the North-East frontier, with the Baungshie, Hlang Tiang, and Tasbon columns (clasp). He was the author of *The Inauguration of War, or Service in the Chin Hills* (1894); and a *Handbook of the Languages of the Lais* (1897).

## Medical News.

As will be seen from our advertisement pages, applications for pensionerships and foundation scholarships at Epsom College must be sent in by the morning of February 18th. An examination is also about to be held for the admission of boys as council exhibitors at the College, applications for which must reach the office, 49, Bedford Square, W.C.1, by the morning of February 18th.

The annual dinner of the Huntarian Society will be held at the Hotel Victoria, Northumberland Arcade, on Thursday, February 12th, at 7.30 p.m. The Lord Mayor and Lady Mayoress of London, the Bishop of London, and several other distinguished guests will be present. The price of the dinner is 12s. 6d. (exclusive of wines). Decorations will be worn.

The second annual evening concert, given by the London Stock Exchange Male Voice Choir in aid of the Royal Medical Benevolent Fund Guild, will be held at Wigmore Hall, Wigmore Street, W., on February 24th, at 8.15 p.m. The choir will be assisted by Miss Phyllis Lett, Mr. Edward Halland, Miss Harriet Cohen, solo pianoforte, and Mr. Leonard Dove, accompanist. Tickets—price 10s. 6d., and 5s. reserved; unreserved, 2s. 6d.—may be obtained from the box office, Wigmore Hall, or from the honorary organizer, Mr. C. Godwin, 10, Drapers Gardens, E.C.2.

At a meeting of the Royal Sanitary Institute, to be held at 90, Buckingham Palace Road, S.W.1, on Tuesday, February 10th, a discussion on food and health will be opened by Major-General Sir Wilfred Beveridge, K.B.E., who will be followed by Dr. W. M. Willoughby. The chair will be taken at 6 p.m. by Dr. Louis C. Parkes.

Dr. MAUD F. FORRESTER-BROWN, M.S., has been appointed for a third year to the William Gibson research scholarship of the Royal Society of Medicine for research in orthopaedics.

THE Fellowship of Medicine announces that Mr. Arthur Giles will lecture, on February 2nd, on the operative treatment of uterine displacements, at 1, Wimpole Street, at 5.30 p.m. During February the following courses will be held: a three weeks' combined course in diseases of children at the Paddington Green Hospital, Victoria Hospital, and the Children's Clinic; a four weeks' course in dermatology at the St. John's Hospital for Diseases of the Skin; a month's course in venereal diseases at the London Lock Hospital (if eight entries are received); and eight clinical demonstrations (twice a week) at the School of Tropical Medicine. In the last fortnight of February there will be a course in general medicine and surgery and the special departments at the Prince of Wales's Hospital, Tottenham. In March there will be a course in diseases of the chest, at Brompton Hospital; in gynaecology, at the gynaeology, at the Royal Waterloo Hospital; in infectious fevers, at the Chelsea Hospital for Women; in infectious fevers, at the North-Eastern Hospital, Tottenham; and an intensive course dealing with medicine, surgery, and the specialties, at the Royal Northern Hospital, with which will be associated the above-mentioned courses may be obtained from the Secretary at No. 1, Wimpole Street, W.1.

THE following courses of lectures will be given at the Aucoats Hospital, Manchester: On Thursdays, February 5th, 12th, and 19th, Mr. Diggle will deal with the diseases of the oesophagus; Dr. Norman Kietz will lecture on dyspepsia on February 26th, March 5th and 12th.

THE Illogan Division of the St. John Ambulance Association has reconstructed its horse-drawn ambulance as a motor ambulance, as a parish memorial to the late Dr. B. J. Mayne. At a meeting of the delegates of the Metropolitan Hospital Saturday Fund held on January 21st, the report of the Distribution Committee recommending awards to participating institutions to the amount of £70,488 was adopted; in 1923 the sum of £71,532 was distributed.

Dr. J. T. WILSON of Bothwell has been presented by his friends with a silver salver and two fruit dishes in recognition of his services rendered to public health during thirty years of office as medical officer of health for the county of Lanark.

THE late Dr. Henry Gervis has left estate of the gross value of £100,457, with net personalty £97,233. He has bequeathed to the Royal College of Physicians of London a miniature on ivory of Dr. William Hunter by Cosway.

THE *Journal of Scientific Instruments*, a monthly publication dealing with their principles, construction, and use, produced by the Institute of Physics with the co-operation of the National Physical Laboratory, and hitherto published by the Institute, will in future be published by the Cambridge University Press on behalf of the Institute.

THE Dr. Sophie A. Nordhoff-Jung prize of 1,000 dollars for the best work on cancer will be awarded in 1926. Further information can be obtained from the Director of the Department of Biology, Georgetown University, Washington.

Dr. E. F. J. PREGRENE, of Gray's Inn, was called to the Bar on January 26th.

IT is proposed to establish a medical college for women in the outskirts of Tokyo, to accommodate eventually about 700 students.

THE Universities Bureau of the British Empire has issued a report enumerating the students from other countries who were enrolled in the Universities and University Colleges of Great Britain and Ireland, in October, 1924. The total number of students so enrolled was 4,385, of whom 1,573 came from Asia, 1,144 from Africa, 794 from America, 564 from Europe, and 310 from Australia; New Zealand, and Fiji. India, Burma, and Ceylon sent 1,199; South Africa and Rhodesia, 747; the United States of America, 425; Egypt, 309; Australia, 188; Canada and Newfoundland, 162; and New Zealand, 121. Many students from other countries study in England without so enrolling; law students and students in technical schools and research institutes are not included in the figures given above. The report contains also a note of the interchange of teachers in 1923-24 between the Universities of Great Britain and Ireland and those of other countries.

On January 21st the death took place at Hatch End of Mr. E. J. Sowerby, chairman of Messrs. H. K. Lewis and Co., Ltd. Owing to failing health he retired from active work in April last. He went to Gower Street in 1872, when Mr. H. K. Lewis was still at the head of the business; from 1880 he was manager under Mr. Morris Lewis; in 1905 a partnership was formed of which he was the senior member. In 1915 the present company was created, Mr. Sowerby being chairman, with the other partners as directors. The interment took place on Monday last at Pinner.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Financial Secretary and Business Manager, 429, Strand, W.C.2, on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—not necessarily for publication.

Communications intended for the current issue should be posted so as to arrive by the first post on Monday or at latest be received not later than Tuesday morning.

The telephone number of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is Gerrard 2630 (Internal Exchange). The telegraphic addresses are:

EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology Westrand, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London.

MEDICAL SECRETARY, Mediscera Westrand, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

"R." asks for advice in the treatment of persistent ulcerative Vincent's angina of tonsil.

#### MOSQUITO BITE.

DR. GERARD C. TAYLOR (Reading), in reply to Dr. Effennell's query (BRITISH MEDICAL JOURNAL, January 10th, p. 95), writes: In my experience the application of solid menthol is effective in allaying the irritation and minimizing the after-effects of a mosquito bite. It should be rubbed well into the punctures and surrounding skin.

#### HERPES AND VARICELLA.

DR. C. H. LAYER (Redhill) writes: I should like to record another case of the coincidence of herpes and chicken-pox. On December 25th, 1924, a lady, aged 60, developed herpes of the right ilio-hypogastric nerve. On January 11th, 1925, her daughter, aged 30, who had nursed her mother, developed chicken-pox. This was a well marked case, the vesicles appearing in crops and running their usual course. There was no history of any contact with chicken-pox.

#### TREATMENT OF TUBERCULOUS MESENTERIC GLANDS.

DR. H. G. FALKNER (London) writes: In answer to "P.'s" question on tuberculous mesenteric glands, I would refer him to Crowde, Hodder and Medical JOURNAL, its Therapeutic Uses, by F. H. Humphris (London: H. Milford, Oxford University Press, 1924, price 8s. 6d.). In sun and day light it would seem to be the ultra-violet rays that are of most importance. These rays have a profound influence on metabolism, raising the power of resistance and stabilizing it. This accounts for the many remarkable results got in most tuberculous lesions. I have seen several cases of tuberculous mesenteric glands completely cured by ultra-violet ray treatment.

### LETTERS, NOTES, ETC.

#### HYOSINE IN PARALYSIS AGITANS.

With reference to the note in our issue of December 27th, 1924 (p. 1222), it should have been stated that the hyosine doses were given twice a day—namely, at 10.30 a.m. and at bedtime—in half a tumbler of water.

#### FREUDIAN DOCTRINE.

SURGEON REAR-ADMIRAL C. MARSH BEADNELL, R.N., writes: May I record my opinion that the question propounded by Sir Bryan Donkin (December 20th, 1924, p. 1177) as to whether or no a discussion of the Freudian doctrine is desirable and practicable should be answered in the affirmative? But as this particular doctrine is but one among many others believed by the majority of scientific and medical men to be based, not on fact, but on unverified assumptions—all of which constitute a challenging invasion of medical territory—I would extend the scope of inquiry suggested by Sir Bryan Donkin to the formation of a committee of leading medical men and psychologists to investigate the claims of the advocates of these doctrines. A published verdict of such a committee would go far to check what can, in many instances, only be described as exploitation of the glibly credulous. As a whole, the medical profession has, through its aloofness towards such doctrines, failed in its duty to the general public. Three culprits—the New Physics, the New Physiology, and the New Psychology—have figured prominently during the last decade, and yet, with certain praiseworthy exceptions, none of

these has been seriously questioned by members of the medical profession. The consequence of this deplorable passivity on the part of medical men is that the general public is in the dark as to their views, and in many instances has been grossly misled. To take but one of these pseudo-sciences as a case in point—the New Physics, or, as better known, the Electronic Reactions of Abrams. This alleged diagnostic and curative system, which involves violation of the known laws of physics and physiology, has for long been suspect, yet we have to thank an American committee for showing up the vaunted reactions as non-existent and the treatment as valueless.

The New Physiology or the New Plasmology, as Sir Conan Doyle has dubbed the "science" dealing with the alleged "psychic" exudation called "ectoplasm," has never been seriously investigated by critics in this country. The New Psychology is a term monopolized by Neo-Freudians in lieu of psycho-analysis, but in it must also be included telepathy, or the alleged sympathetic action between two "minds"; telekinesis, or the alleged power to move material objects by "thought" alone; and cryptesthesia, a faculty of cognition claimed by Richet to be dependent on extrasensory channels of knowledge. Each of these cults has its famous apostles, yet none of them has been subjected to systematic investigation. It may be said that if a person states that dragons inhabit the centre of the earth the onus of proving their existence is on him and not on his critics, otherwise medical men, psychologists, etc., would be frittering away their time in discussing the reactions of lunatics and impostors. When credulity is the result to the community, as the profession voiced its verdict.

#### LONG FREEDOM FROM RECURRENCE AFTER OPERATION FOR CANCER OF THE BREAST.

DR. JOHN BROWN (Blackpool) writes with reference to Mr. Steward's case of cancer of the breast in a woman aged 81 years (January 24th, p. 156): I consider the conclusion drawn, that the four cancerous nodules in the scar were connected with the cancer removed thirty-one years before, is fairly open to question. Cancer in persons over 75 is due to degenerative changes in the epithelial cell, and in many cases they are very slow in growth, usually painless, and may be looked upon as a form of natural decay. We know that scar tissue is predisposed to cancerous degeneration. I would call the attention of your readers to an interesting case of chronic cancer of the breast, who died at 97 years of age, recorded by Sir J. Rickman Godlee; there were no enlarged glands. The specimen is in the Royal College of Surgeons of England, Lincoln's Inn Fields, No. 1,774.

#### AN OPERATION AND AN OBSERVATION.

DR. JOHN B. NASH (Sydney, New South Wales) writes: In the Mackenzie Davidson Lecture by Sir Thomas Horder (BRITISH MEDICAL JOURNAL, July 19th, 1924) he is reported to have said:

"In reference to operations may I, in passing, share the lament of Sir James Mackenzie that hitherto so little has been done by way of

Several years ago, in conjunction with Drs. Crawley and Dunlop, I attended a medical man in Newcastle. He was desperately ill with double pneumonia and following streptococcal peritonitis. After about three most anxious and arduous weeks for physicians and nurses, the patient began to recover. Several times since then I have heard the local physicians say: "Pituitrin saved the patient's life." Recently I was operating upon a man, aged 58, for a large tumour of the upper third of the neck between the superficial layer of the deep cervical fascia and the prevertebral layer of the same fascia. The necessary procedure included the cutting of the sterno-mastoid muscle in its lower third, the clamping of the carotid artery, the ligaturing of the jugular vein, the separating of the pneumo-gastric nerve from the other contents of the vascular sheath, the lifting of the tumour from its bed on the prevertebral fascia and muscles. The excised mass consisted of the sterno-mastoid muscle, the tumour, the internal jugular vein, the common carotid artery, the external and internal carotid arteries. When this mass was lifted free I drew the attention of my assistants to the regular and forcible pulsation of the tied stump of the common carotid artery, below the omo-hyoid muscle. The anaesthetist said: "He has just been given a dose of surgical pituitrin." The deduction is that the pituitrin dose was just enough to promote the required systoles in the heart muscle, while allowing of the diastoles in regular sequence. The pulsations sent my memory back to the medical man and his desperate illness, and to the pituitrin which made his unstripped intestinal muscles act forcibly enough to empty freely his distended intestinal tract, thereby ensuring his recovery.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 33, 36, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 34 and 35. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 55.

## Presidential Address

ON

## RECENT ADVANCES IN THE STUDY OF CARDIO-VASCULAR DISEASE.

DELIVERED BEFORE THE ULSTER BRANCH OF THE BRITISH  
MEDICAL ASSOCIATION, NOVEMBER, 1924;

BY

J. E. MACILWAINE, M.D., B.Sc., D.P.H.,

VISITING PHYSICIAN, ROYAL VICTORIA HOSPITAL, BELFAST; PROFESSOR  
OF MATERIA MEDICA AND THERAPEUTICS, QUEEN'S UNIVERSITY,  
BELFAST.

THE word "study" in the title of this address has been used with the idea that the address may cover a considerable amount of matter which has not as yet, perhaps, reached its full practical utility. I shall endeavour, on the other hand, to discuss the questions taken up in as practical a manner as possible. The period taken as being covered by the term "recent" is merely defined by the period since my own graduation in medicine—twenty-three years. I had intended to give some points with regard to the history of the study of cardio-vascular disease, but time will not permit more than a mention of a very few names.

I think it may be said that four hundred years ago Harvey laid the basis of all real study of cardio-vascular disease. Before his time the views held on the mechanism of the circulation were so speculative and so dissociated from reality that it is difficult to-day to conceive how such ideas could exist.

About a hundred years ago auscultation had led to a definite recognition of the origin and cause of the first and second sounds of the heart, and the question of murmurs was being thoroughly investigated. Just seventy years ago E. J. Marey<sup>1</sup> began the development of his instrumental methods, based upon air transmission of pulsation, and opened up entirely new ground with regard to the study of cardio-vascular disease.

Broadbent's book on the diseases of the heart, published in 1897, might be considered representative of the position of clinical cardiology just before the period termed "recent." I left the Royal Victoria Hospital at the beginning of this period, having had, under Professor Lindsay, as good an opportunity of learning cardiac work as any young graduate could desire.

It is proposed to consider the recent advances under four heads:

- I. Advances in the study of the mechanism of the circulation.
- II. Advances in knowledge of the functional activity of some of the organs of the body, obtained by recent biochemical methods.
- III. Altered views, from a bacteriological and pathological standpoint.
- IV. Recent pharmacological development.

### I. THE CIRCULATORY MECHANISM.

In considering the circulatory mechanism the first point we must take up is our altered view of the mechanism of the heart-beat. This alteration of view means that to-day we recognize the sinus node at the venous-auricular junction as the "pace-maker" of the heart. This node throws in its impulses with the regularity which constitutes the "dominant rhythm of the heart." These impulses start the waves of contraction which flow over the auricle to arrive at the A-V junction. Here they encounter the auriculo-ventricular node, and, through this node, transmit their stimulus down the right and left branches of the auriculo-ventricular bundle. Each A-V branch goes to its respective ventricle, terminating in the Purkinje's fibres, thus constituting a conducting system, which apparently stimulates the true cardiac muscle to contract.

In 1801, when studying at the Nothnagel clinic in Vienna, I took a course upon cardiac disease, and in no part of the course was there any discussion whatever of the analysis of a single heart-beat, although in the textbook recommended (Sahl's *Untersuchungs Methoden*) as an appendix

there was a discussion, with pulse tracings, of the irregular pulse. The analysis of Wenckebach and Engelmann separated the irregular pulse, due to the extra-systole, from the completely irregular pulse, which we now know to be due to auricular fibrillation.

Then came the epoch of Mackenzie's work, which dominated all clinical cardiology. It was based upon the analysis of the single heart-beat, using for this purpose the jugular pulse or venous tracing, correlated with the arterial pulse, etc.<sup>2</sup> If we examine the venous tracing we find that there is a wave which synchronizes with the time of contraction of the auricle, and Mackenzie noted that this wave had disappeared when complete irregularity of the pulse existed. He established definitely that the auricle was not working normally under these conditions. It was left, however, for Lewis to demonstrate that the auricle was fibrillating, but Mackenzie's work placed cardiology upon a new basis, and definitely gave us a true classification of the cardiac irregularities. Auricular flutter had been previously recognized by Ritchie and Jolly, by aid of the electro-cardiograph. Clinical electro-cardiography, which will always be associated with the name of Thomas Lewis,<sup>3</sup> has introduced into medicine an entirely new method of examination—namely, a graphic record of an electric pulsation in the body, which is synchronous with the passage of the wave of contraction over the heart muscle. These graphic records gave us the foundation of our classification of cardiac arrhythmias—namely, sinus arrhythmia, the auricular extra-systole, the ventricular extra-systole, auricular fibrillation, and auricular flutter, together with complete and partial heart-block. The newer method of electro-cardiography gives a further indication which has been interpreted as the occurrence of a block in the conducting system of the heart beyond the auriculo-ventricular junction—namely, in one of the branches of the A-V bundle; that is, either to the right or left ventricle. The electro-cardiogram presents another physical sign, inasmuch as the wave which synchronizes with the ventricular contraction in the heart, the T wave, may become altered, or inverted. This inversion or negativity of the T wave, which occurs in certain electro-cardiographic tracings, has been shown statistically to be a physical sign of grave import in cardiac prognosis (Willius<sup>4</sup>). Thus from the study of the mechanism of the heart-beat knowledge has been obtained which has given a definite classification of the cardiac irregularities, and also definite indication of lesions of the heart which involve the conducting tissue in that organ.

Taking up next the consideration of the mechanism of the circulation in the arteries, blood pressure has become such a well known phenomenon, even amongst the lay public, that it is necessary to say something regarding its estimation. About 1827 it became a clinical method, and Riva-Rocci in 1897 designed the instrument which is probably most used to-day in clinical work. In 1905 Korotkow introduced a method for estimating the diastolic pressure. The estimation of the systolic pressure is easily carried out. Our ability to estimate correctly the diastolic pressure is not unchallenged. In most cases, when using the auscultatory method, there is a distinct sudden change in the character of the "knock" heard over the brachial artery, and I think the record of this point of change as the diastolic pressure is most valuable. Macleod, in his *Physiology*,<sup>5</sup> states that the diastolic pressure is the dead load of the circulation, and is the pressure which the aortic cusps, great vessels, and arteries have got continually to bear. I consider a diastolic pressure which is permanently raised is of much prognostic importance, and it is sometimes relatively unaltered when there is a marked fall of the systolic pressure.

It has been recognized that a single estimation of blood pressure may give a wrong idea of the condition present in some patients. It may be necessary to chart daily the record of blood pressure in order to note how variable it is. A variation of 60 mm. of mercury in the systolic pressure may be seen in forty-eight hours. The difference in millimetres of mercury between the systolic pressure and the estimated diastolic pressure is called the "pulse pressure." This observation is used clinically, but we do not as yet know quite how to assess its true value. I have always thought that the great difficulty in regard to pulse pressure is the

fact that we are unable to obtain a true curve of pulse pressure. We have but two points on this record—namely, the systolic and diastolic pressures—but we have no intervening curve upon a true time base. It would only be by obtaining such a curve that we could integrate this true pulse pressure into work.

Very recently the anatomy and physiology of the capillaries have been studied by Krogh,<sup>6</sup> and his work, in connexion with that of Dale and others, makes it perfectly clear that a capillary paresis, or a filling up of the capillaries of the body with blood, may be the source of a circulatory failure. Thus we have the picture of traumatic and histamine shock, where the arterial system is insufficiently filled because the heart lacks a proper supply of blood from the veins. In other words, the heart is beating rapidly, but receiving relatively little blood, because of the lagging of blood in the capillary system of the body. We must bear this in mind when considering the question of toxic death. It is not sufficient simply to say "cardiac failure" and think that means a failure of the cardiac muscle, any more than that this muscle is, like the rest of the tissue of the body, insufficiently supplied with blood, owing to a lack of blood volume in the arterial system. The treatment of such cases in surgery has to-day become a matter of filling up the circulation by the transfusion of blood or gum saline, etc.

Under the head of the circulatory mechanism we must consider the altered views which a knowledge of the involuntary nervous system, such as presented by Gaskell,<sup>7</sup> brings with it. From the diagram it is seen that the vagus and

Autonomic Nervous System.

pelvic nerves represent the cranial and the sacral outflow of involuntary nervous impulses; they go, in the case of the vagus, to the heart, lungs, stomach, and small intestine, as far as the ileo-caecal valve; whereas the pelvic nerve, or sacral outflow, goes to the colon and the genito-urinary system. These nerves are opposed in their action by what we used to call the sympathetic system, and are often spoken of as parasympathetic nerves. The sympathetic system is that portion of the involuntary or autonomic nervous mechanism which comes from the thoracico-lumbar cord. This sympathetic sends fibres to the heart, lungs, stomach, small intestine, large intestine, genito-urinary system, etc., to antagonize the parasympathetic fibres. We have only recently begun to grasp the clinical meaning of this involuntary neuro-muscular mechanism. When dealing with the problem of D.A.H. (disordered action of the heart) it seemed, at the end of the work which had been carried out, that an explanation of this condition might lie in an instability of this involuntary neuro-muscular mechanism. So much was I impressed with this instability, which appeared to be either inherent or toxic in origin, that I could not help thinking how often in common language the actions of this involuntary mechanism are expressed. Thus we remember the expressions "He has no heart"; "He has no stomach for the fight"; "He has no guts"; and it is well recognized how uncontrolled the sphincters may be as the result of emotion. Further, these involuntary reactions upon an emotional basis bring into consideration their association with the secretions of the endocrine glands. While these ideas are yet speculative and theoretical, out of the knowledge of the autonomic nervous system of the heart there has come a more dramatic picture; and here one must allude to Sir James Mackenzie's work upon the segmental association of the pain reflex and visceral sensations in the spinal cord. In the recently published monograph on *Angina Pectoris*<sup>8</sup> we see this work in its true perspective and are able to appreciate the

practical application of his principles in classifying the condition into a "primary" and a "secondary" form. It was upon this same subject—the interrelation of visceral and somatic sensation—that Dr. Ivy Mackenzie touched when speaking in this hall in the spring of this year. In his paper "The reactions of the ulnar nerve in disease" we have a good example of how modern advance in neurology can illuminate a clinical problem. Professor Danileopol's paper in a recent number of the *British Medical Journal*<sup>9</sup> discusses the surgical treatment of angina by section of afferent fibres from the heart in the involuntary nervous system. One interesting idea arising from the consideration of Professor Danileopol's diagram is the vasomotor reflex from the heart acting upon the lungs. It may, perhaps, aid us theoretically to explain some of the cases of cardiac asthma in which, apparently, no real anoxaemia is present. I would utilize this conception of the relation of heart with stomach and intestine through the involuntary nervous system to impress upon you the importance of dietetic treatment in cardiac cases. How much more we will get out of our study of the involuntary system it is difficult to foresee, but I believe that clinically it will be more and more helpful in the solution of problems which to-day are unsolved.

## II. BIOCHEMICAL TESTS AND FUNCTION.

As a result of biochemical methods Hill, Meakins, and other observers have been able to give us figures of a most illuminating character with regard to the volume of blood which flows through the heart in a minute. Roughly, in a man at rest, a normal heart may pump about 7 litres of blood through in a minute. By active exercise this can be increased up to 30 litres. The exact amount per heart-beat is thus easily calculated. When there is failure of compensation, Meakins<sup>11</sup> has shown that, in spite of a large dilated heart, the minute-volume may be as low as 2½ litres; and he further demonstrated, in some of Ritchie's<sup>12</sup> patients, that as failure increased this minute-volume diminished. These figures allow us to appreciate what cardiac decompensation really means, and let us visualize the importance of absence of *vis a tergo* when we discuss "back pressure" as an increased resistance to the onflow of the blood. Did we know the exact volume of blood per heart-beat, and had an exact time record of aortic and pulmonary pressure, we could state in absolute mechanical terms the work of the heart. These figures are not yet clinically available.

Another advance in the study of cardio-vascular disease has been that biochemists have placed at our disposal methods of estimation of renal function which enable us to diagnose the presence of renal disease. To see clearly a cardiac condition which is associated with renal inadequacy is a great help in diagnosis, and also, necessarily, in treatment. I would only mention that the choice of a diuretic, if a diuretic is to be used at all, must largely be governed by our knowledge of the state of the renal function.

The third biochemical assistance in cardio-vascular disease is that by estimation of the metabolic rate a firm basis is given which determines whether hypothyroidism is present, and somewhat gauges the extent. Recent work on the thyroid has tended to separate a group of thyroid patients in whom the condition is to be described as that of a toxic adenoma of the gland. It would appear that a toxic adenoma is practically a malignant condition. Gradually the intoxication increases, and relentlessly the cardiopathy progresses. A clear case would seem to be made in this condition for early removal of the "malignant" tumour.

## III. PATHOLOGY AND BACTERIOLOGY.

Under this heading let us first consider the rheumatological heart. This has been well described from a pathological point of view by Carey Coombs,<sup>13</sup> who puts forward as clearly the observation that in this pancarditis, as I, and, it, the myocardium is always markedly involved, just as joints and subcutaneous rheumatic nodules disappear. These submiliary myocardial nodules tend to disappear without much injury to the muscle, whereas in possible and vascularized endocardial valves resolution is impossible and cicatrization results. These pathological facts alone are

sufficient to emphasize the necessity of prolonged rest in children who have had rheumatic infection. In fact, the suggestion of sanatorium treatment and notification of acute rheumatic infection is well worthy of consideration.

Next the syphilitic heart. Here the pathology of the arterial change and the recognition of the involvement of the myocardium as well as the great blood vessels, in this progressive lesion, makes it a great additional advantage in prognosis and treatment of cardiac cases to obtain the evidence of a positive Wassermann reaction.

Horder and Libman<sup>14</sup> separate a group of cases of subacute infective endocarditis with very definite clinical signs such as described by Cotton<sup>15</sup> and others. Under the title "endocarditis lenta," Starling<sup>16</sup> and Carey Coombs<sup>17</sup> have presented groups of cases of unusual interest; and if this condition, which anyone connected with cardiac work must have seen, is to be associated with an enterococcal type of infection we have an etiological asset of great importance. Unfortunately, so far the treatment of these chronic endocarditis cases has been practically hopeless.

#### IV. PHARMACOLOGY.

My fourth and final point with regard to advance is the consideration of the pharmacological aspect of cardiac disease. I do not intend to do more than indicate briefly the changes which have taken place with regard to teaching concerning remedies in common use. This group of scientists, the pharmacologists, are pushing steadily ahead, and to-day the student is taught, from a pharmacological point of view, what is the site of action of the remedy he is going to use. In such a subject, so recent and rapid in its development, we are bound to find unconfirmed statements and controversial points; but I believe that, just as physiology has now laid the recognized basis of our clinical teaching in medicine, so will pharmacology be the recognized basis of teaching of therapeutics. Pharmacologists are extending their sphere of action into consideration of problems of immunity, and one hopes that in this field they will equally show their powers of advance. To take, as an example, digitalis, its mode of action and its contained glucosides are to-day more fully understood, and thus we teach that its greatest advantage in therapeutics is the slowing of the ventricle, mainly by the depressing of conduction from auricle to ventricle. Or, again, one may consider the change of method of the administration of digitalis, as suggested by Eggleston, in large doses—a drachm and a half, followed by a drachm in six hours, and a drachm six hours later. The success claimed for this method will teach us not to rely upon small doses in urgent cases, but it is also well to remember that we must always standardize our doses of digitalis by observation of the patient.

One or two points on which we have pharmacological backing are: that calomel need not be avoided as a diuretic in renal disease associated with cardio-vascular change and oedema; that morphine, in medicinal doses, has practically no effect upon the cardiac muscle; it has a central or cerebral depressant action of enormous value; it does not influence to any extent the kidney secretion, and, except where respiratory depression must be avoided, can be given with safety in all cardiac cases.

Quinidine, a remedy of very recent introduction, is still under judgement. One point the pharmacologists have told us is that it is a depressant of the cardiac muscle, and experience has shown that we must carefully control its administration as it quickens the ventricle in the majority of cases. These two facts are most important where there is any question of the likelihood of failure of compensation. The use of adrenaline in Stokes-Adams disease, as suggested by Parkinson, and in the sudden cardiac emergency of chloroform poisoning, must also be noted. What exactly is the effect of pituitrin on capillary paresis has yet to be tested out.

There is no doubt that the work which is being undertaken from a pharmacological point of view will give us back, with a renewed confidence in them, many remedies which have been neglected.

In concluding this attempt to review some of the recent advances in the study of cardio-vascular disease it might be

said there are two distinct lines upon which progress has been made. The increase of knowledge of structure, mechanism, and function gives us a better basis for the recognition of the changes produced by disease—that is, an increased refinement of diagnostic classification. If, on the other hand, we assume that the incidence of the disease precedes these recognized changes, a point Sir James Mackenzie emphasizes, we will appreciate how developments in the study of etiology and immunity will bring with them a hope of new therapeutic methods.

## Lectures

ON

## THE SYMPATHETIC INNERVATION OF STRIATED MUSCLE.\*

BY

THE LATE JOHN IRVINE HUNTER, M.D., CH.M.,  
CHALLIS PROFESSOR OF ANATOMY IN THE UNIVERSITY OF SYDNEY.

### LECTURE II.—PART I.

### THE FUNCTIONS OF THE TWO GROUPS OF MUSCLE FIBRES:

#### EXPERIMENTAL EVIDENCE.

In the first lecture I submitted the evidence that has accumulated during the last half-century in demonstration of the fact that the striated muscles of vertebrates consist of two kinds of fibres (in addition to the muscle spindles) and that the difference in their innervation is as distinct as the contrast in their anatomical features, one group being controlled by the spinal cord through medullated somatic nerves, the other by the central nervous system through the intermediation of the sympathetic system, the post-ganglionic non-medullated grey rami communicantes.

In the present lecture I propose to discuss the evidence obtained by cutting the sympathetic and the somatic nerves respectively in proof of the fact that the functions of the two groups of muscle fibres are as sharply distinguished as their structure and mode of innervation. Our preliminary experiments were made upon goats, not only because they are large animals with the simplest type of "standing reflexes," but also because Royle and I had acquired some experience of these animals under experimental conditions in the course of our investigations on spinal shock in 1920 and 1921.

The details of the experiments upon the goat have been given in the earlier accounts of our work in the *Medical Journal of Australia*. I can more usefully employ the time at my disposal in these lectures to explain the principles that guided us in our work and to discuss the results and certain technical points that throw light upon the issues in the present controversies.

In Fig. 3 the essential connexions of the sympathetic system are represented in a purely diagrammatic way. The white rami communicantes that issue from the spinal cord in the thoracic and upper lumbar region end in the ganglia of the sympathetic cord (or in one of the peripheral ganglia not shown in the diagram). From the sympathetic ganglion two series of non-medullated nerves emerge—one proceeding directly to the viscera of the thorax and abdomen, the other, forming the grey rami communicantes, passing to the

\* Delivered by Professor Elliot Smith at University College, January 26th, 1925.

mixed nerve, to reach the striated muscles (*inter alia*) along with the somatic motor nerves.

By cutting the grey rami communicantes at A (as it should be the surgeon's aim to do in all human operations on the sympathetic) sympathetic innervation of the muscles in the area of distribution (as well as of the blood vessels

FIG. 3.—Diagram of the essential sympathetic connection.

and sweat glands) is destroyed, but the sympathetic ganglion and the visceral nerves are left undisturbed, and the patient is spared the unfortunate effects of loss of proper control of visceral function, to which he is rendered liable when the sympathetic ganglia are needlessly removed. But for experimental purposes it is often necessary to cut the white ramus at B, and this is also done occasionally (for reasons to be explained later) in human patients. In this case the efferent channels from the spinal cord to the sympathetic cord are severed, not necessarily, nor even usually, to the ganglion (as Fig. 3 might suggest) that the ramus enters immediately, but to some part of the ganglionic cord or one of the peripheral ganglia. In this case, as also in those cases where the sympathetic ganglion itself (at C) is cut or excised, the activity of both the visceral branches and the grey ramus is eliminated. The somatic efferent nerve may in some cases be cut at E without interference with the sympathetic ramus. Another type of experiment—the section of the posterior root at D—cuts off all afferent impulses, both somatic and splanchnic. As the tone of muscle depends upon reflex activity, cutting off the afferent limb of the reflex arc destroys tone equally with damage to the efferent fibres (somatic at E, or sympathetic at A, B, or C).

In the human patient the grey and the white fibres may be so intermingled in the lumbar region as to make it impracticable wholly to spare the white fibres in the operation that Royle has called "ramisection."

With reference to the procedure for removing the influence of the sympathetic system on the hind limb of a mammal or the human leg, I cannot put the essential points more clearly than Royle has already done in his part of the Murphy Oration, illustrating the account with drawings (Fig. 4) made from the excellent dissection by Dr. T. K. Potts of Sydney (see *Journal of Anatomy*, January, 1925).

In experimental animals the sympathetic influence was removed from the left lower limb simply by avulsing the left abdominal sympathetic trunk. This operation could not be considered in the human subject on account of the changes that would follow removal of the sympathetic nerves to the abdominal viscera. The sympathetic nerves supplying the muscles of the lower limb arise from the lumbar ganglia and pass through the rami communicantes to the mixed nerves of the lumbosacral plexus. The human sympathetic ganglia receive white (preganglionic) fibres in some cases as low as the third lumbar nerve. Usually the contribution of white nerves to the sympathetic system ceases at the level of the second lumbar nerve. The dis-

tribution of white and grey rami in this situation is impossible, as it has been shown by N. Bishop Harman that the rami of the second and third nerves may contain both white and grey fibres. The sympathetic supply to the abdominal viscera is given off from the ganglionated trunk in a medial direction, and, provided the operation of ramisection were confined to lateral branches directed from the sympathetic trunk to the second, third, and fourth lumbar nerves, the effect upon the abdominal organs would be negligible. The division of the sympathetic supply to the fifth lumbar and to the sacral nerves presented a more difficult surgical problem, but this solved itself easily, because the sympathetic supply of the viscera is usually given off above the level of the fifth lumbar nerve and complete division of the sympathetic trunk at any point below the level of the fourth lumbar nerve would not affect the viscera. The sympathetic ganglia are not regular structures and do not always correspond in position to the lumbar nerves. The first ganglion usually lies in relationship to the second lumbar vertebra or the intervertebral disc below this vertebra. Below this the trunk may have three or more ganglia. There may, however, be only two definite ganglia.

The plan Royle adopted in the first operation was to divide the rami communicantes of the second, third, and fourth lumbar nerves (at the points marked A, B, and C in Fig. 4, the letters being used with the same significance as in Fig. 3), and to divide the sympathetic trunk at a level corresponding to the fourth lumbar vertebra (C). The

FIG. 4.—Drawing to represent the arrangement of the rami communicantes passing to the left lumbar nerves in man. After Dr. T. K. Potts. The black bars represent the places where avulsion is effected in the operation of "lumbar ramisection." The letters will facilitate the interpretation (with the help of Fig. 3), A being a grey ramus, AB a mixed ramus, and C the sympathetic cord.

exact level of section must depend, however, upon the presence of a ganglion in this situation, and also whether that ganglion is supplying any medially directed fibres.

The ganglionated trunk itself is a very variable structure, and this particularly applies to the region of the fourth lumbar vertebra. On many occasions the trunk in this

situation has been found to divide, and it was difficult to decide which division continued downward as the main trunk. The plan subsequently adopted was to define the ganglion which gives grey rami to the fourth lumbar nerve, lift it from its bed, and remove its lateral, posterior, and inferior connexions. Any medial fibres should be carefully preserved. When this ganglion is not present the ganglion supplying the third lumbar nerve may be unusually large and supply rami to the third and fourth nerves. The size of the ganglionated trunk may vary on each side of the body, and the rami may or may not come from the region of the ganglia.

The size of the rami varies with the number. A single ramus supplying a single nerve may be 2 mm. in diameter, though the usual size of a ramus varies between 0.5 and 1.5 mm. The accompanying diagram (Fig. 4) shows that the lumbar ganglion corresponding in position to the second lumbar nerve receives a large white ramus from the first lumbar nerve. In Royle's series of forty-two lumbar operations this arrangement was almost invariable; in only one instance was this large branch absent. In the first operation this ramus was mistaken for the white ramus of the second lumbar nerve and was divided, but subsequently the ramus has been avoided unless a special therapeutic effect was sought. In every operation both the white and grey rami of the second lumbar nerve have been divided. The position of the ganglia may cause considerable variation in the position and direction of the rami, but, with the exception mentioned above, the rami tend to travel laterally or laterally and downward.

The operation of cutting these three rami and the sympathetic cord at a lower level Royle has called "lumbar ramisection." The procedure for severing the sympathetic supply to the arm he calls "cervical ramisection." In this case the operation can be strictly restricted to the grey rami communicantes without cutting any white fibres or the ganglionated cord of the sympathetic. In Fig. 5 a drawing of Potts's dissection is shown.

The sympathetic trunk does not come into the field of operation excepting in the approach to the first thoracic nerve. The rami above the first thoracic nerve are composed wholly of grey (post-ganglionic) fibres, but the first thoracic nerve itself usually has both a white and a grey ramus. The sympathetic rami as a rule enter the nerve roots of the brachial plexus after they emerge from the intervertebral foramina, though occasionally rami will be found joining the nerve roots within the foramina.

According to the description of normal anatomy the nerve roots of the brachial plexus should emerge between the scalenus anticus and the scalenus medius muscles. In operations Royle says it is exceptional to find this arrangement. It is much more common to find the fifth and sixth roots piercing the scalenus anticus, and in several instances these roots have appeared anteriorly to the muscle. The seventh nerve also is commonly separated from the eighth by a bundle of muscle fibres. The eighth and the first thoracic nerves usually emerge together in a plane posterior to the scalenus anticus. A regular plexus considerably simplifies

the operation, while the difficulty is increased if each nerve root emerges separately through the scalenus anticus.

All the grey rami proceeding to the roots of the brachial plexus are easily broken with a small strabismus hook in the operation of cervical ramisection. The grey ramus to the first thoracic nerve is found on the upper surface of the latter on the medial side of the white ramus (Fig. 5), cutting of which should be avoided if possible.

I have referred to the nature of the operations at this stage to give a precise idea of what actually is done. In the third lecture I shall return to the consideration of the indications for operation . . . of the choice of these rami for avulsion . . . this I must discuss the experimental . . . functions of the two kinds of striated muscle.

Instead of describing the details of the experimental technique, which have been published in the memoirs already mentioned, I prefer to discuss the reasons for such extreme diversities of opinion as to the influence of the sympathetic nerves on striated muscle. This may be most profitably done by discussing certain points in experimental technique—such as (a) the reasons for allowing a considerable interval

to elapse after removing the sympathetic before performing the operation of decerebration; (b) the method of examination of the animal so as to eliminate the disturbing effects of fear upon muscular tone, or the labyrinthine and cervical influences investigated by Magnus and de Kleijn; (c) avoidance of the effects of asphyxia and of anaemia of the brain-stem in decerebrate animals; and (d) the important matter of the choice of animals for experimentation. The latter two points—(c) and (d)—will be discussed in the third lecture. In this lecture I want to direct attention to the important information

obtained from my experiments on birds, most of which has not hitherto been published, although passing references have been made to the preliminary results in the *Medical Journal of Australia* (June 14th, 1924, p. 581) and in *Surgery, Gynecology and Obstetrics* (December, 1924, p. 724).

#### THE FUNCTION OF THE SYMPATHETIC INNERVATION OF STRIATED MUSCLE.

In 1913 de Boer, as the result of experiments upon frogs, claimed to have shown that the sympathetic nerve supply of skeletal muscle was concerned with tone. He believed that the tone of striated muscle was governed exclusively by its sympathetic nerve supply. All subsequent workers have shown that this contention is untenable; and many of them have gone to the other extreme and denied any influence of the sympathetic on muscle tone. The truth certainly lies between these conflicting claims. De Boer's view is being replaced by the conception that only a certain element of muscle tone owes its origin to the sympathetic nervous system. In 1915 Langelan advanced the view that the tone of skeletal muscles consists of two elements, one component being governed by the somatic supply and the other by the sympathetic innervation of the muscle. This conception was independently arrived at by Revon. Later,

FIG. 5.—Drawing of the left brachial plexus in man to show the position of the grey rami communicantes which are avulsed in the operation of "cervical ramisection." After Dr. T. K. Potts.

Langelan (1922), as the result of experiments on frogs, added further evidence in corroboration of this opinion. He failed, however, to clear away the fundamental objection to the acceptance of his theory—namely, that no investigator had shown tone to be altered consistently in decerebrate preparations as a result of sympathetic denervation; or, conversely, that decerebrate rigidity could develop if the sympathetic innervation were left intact while the somatic nerves were severed.

The importance of decerebrate preparations consists in the fact that, from their study in the hands of Sir Charles Sherrington and others, most of the prevailing ideas of muscle tone have been derived. Sherrington proved that the tone of skeletal muscle was postural in function. He found that the typical position of the decerebrate animal was that of "reflex standing," with all four limbs rigidly extended, and the neck retracted to a greater or lesser degree. Between the phases of rigidity there were periods in which the limbs were no longer maintained in extension. During these periods, or when the extension of the limbs was overcome by passive movement, the musculature was found to exhibit a condition of what Sherrington has called "plasticity." If the leg were flexed at the knee, so lengthening the extensor muscle of the thigh, this position was retained ("lengthening reaction"). If the knee were now extended, so shortening the extensor muscle, the new position was again maintained ("shortening reaction"). Sherrington called the property of skeletal muscle which enabled it to exhibit these reactions "plastic tone." He emphasized that the degree to which this property was exhibited was independent of the length of the muscle fibres exhibiting it. It is important to remember that Sherrington was not using the word "plastic" in the popular sense of being adaptable or easily moulded; what he meant by it was the retention of any position in which a limb was placed. Following the suggestion of Grunetzner and others, he compared this property of skeletal muscle to that of involuntary muscle, such as that which surrounds the bladder wall, which enables it to adjust itself to enclose an increasing volume under practically the same wall tension. Speaking of this comparison Sherrington says: "Both are instances of the postural contraction of muscle; though the relation of the central nervous system to the postural activity is very different in the two cases." For Sherrington believed that the tone of striated muscle was entirely dependent on the intactness of the somatic motor nerve supply, while involuntary muscle can exhibit tone in the absence of its innervation.

The objection to the view that the tone of skeletal muscle is partially governed by the sympathetic nervous system, which has been put forward because experimenters employing the decerebrate preparation have obtained negative or apparently inconsistent results, disappears with the publication of our experiments (the memoirs of Royle and myself). In this work evidence of the connexion of the sympathetic innervation with the tone of skeletal muscle is forthcoming, not only from experiments upon the decerebrate goat, but from the effect of sympathetic ramisection in patients suffering from forms of spastic paralysis, which prior to operation revealed all the essential qualities of decerebrate rigidity. In normal, "spinal," and "decerebrate" animals, and in human patients, sympathetic denervation of the limb musculature led to a consistent qualitative alteration in muscle tone. The defect was found to be a lessening of the efficiency of the muscle in maintaining a position once it had been assumed. This was the case whether the position had been imposed passively, reflexly, or by voluntary contraction; and, as I have previously argued,<sup>11</sup> is due to the same fundamental change—namely, the loss of plastic tone. In the decerebrate preparation, after passive movement, the limb deprived of its sympathetic innervation failed to maintain the new position imposed upon it, when the extensor muscles were either lengthened or shortened. Instead, the limb would fall back to a posture determined by the action of gravity and the length of the fibrous tissues entering into its composition. This illustrates the effect of sympathetic denervation to remove plastic tone, as evidence of which is the absence of the "lengthening and shortening reactions" of

Sherrington. The skeletal muscles of human patients show a similar qualitative alteration. This is clearly shown, for instance, in one of Dr. Royle's patients with spastic paraplegia supervening upon a gunshot wound of the cerebral cortex. Prior to operation this patient clearly exhibited "lengthening and shortening reactions" of the extensor muscle of the knee. Before operation, if the left thigh were lifted from the bed the unsupported leg would remain extended for a long period of time. If the extended leg were passively flexed at the knee-joint it would remain flexed in its new position. If it were now passively extended the extended position would be maintained. After left lumbar sympathetic ramisection these reactions, which are identical with the "lengthening and shortening reactions" of the decerebrate preparation described by Sherrington, were no longer exhibited—that is, plastic tone was removed by the operation.

But it is important to notice that tone does not entirely disappear after sympathetic denervation. Only one efferent pathway to the skeletal muscle has been removed (compare Fig. 3). The remaining somatic innervation is responsible for another component of muscle tone. In the acute decerebrate preparation, for instance, notwithstanding the removal of its sympathetic nerve supply, the typical extensor attitude of the limb is assumed. The neuromuscular mechanism concerned in imposing the extended position is obviously intact—that is, the medullated somatic nerves are responsible for this function. It will readily be seen that the extensor muscles must be shortened in order that the extensor attitude of the limb may be attained. The antagonistic muscle groups, on the other hand, are reflexly inhibited, as Sherrington's studies of the acute decerebrate preparation have shown. Their component of tone, which is somatic in origin, and is exhibited as a degree of contraction of selected muscle groups, may, following Langelan, be called "contractile tone."

Contractile and plastic tone are both postural in function. Contractile tone imposes posture as a result of shortening of appropriate muscle groups; plastic tone takes part in maintaining this posture, once it has been attained, by fixing the length of the muscles exhibiting contractile tone. On account of the responsibility of these two components of tone in the production and maintenance of posture they may together be regarded as constituting postural tone.

As Sherrington has shown (by cutting the appropriate afferent nerves) the production of postural tone depends upon the existence of proprioceptive impulses. Posterior nerve root section in all the spinal segments connected with a given muscle removes both contractile and plastic tone. Impulses arising in the muscles, therefore, discharge (via the central nervous system) through both the somatic motor nerve roots and the white rami of the sympathetic nervous system. In other words, contractile tone is subserved by a somatic proprioceptive reflex arc; plastic tone is governed by a sympathetic reflex arc. As the result of the limited connexions of the sympathetic nervous system with the spinal cord, these reflex arcs for a given muscle group are usually situated at different levels of the central nervous axis. Purely spinal reflexes are, however, inadequate in higher vertebrates for the exhibition of the postural tone responsible for the natural attitudes of the body. The reflexes responsible for the extensor attitude of the lower extremities depend, for instance, upon reflex arcs that pass as high as the pons in the brain stem. It appears that the vestibulo-spinal tract is the descending limb of the reflex arc subserving the contractile tone to the extensor muscles of the limb; while plastic tone depends upon a reflex arc the descending limb of which is constituted by the ponto-spinal tracts. I have recently argued<sup>12</sup> that these reflex arcs are governed by the tectum, substantia nigra, and red nucleus of the mid-brain, and the corpus striatum and the cerebral cortex by way of the cerebellum. The influence of all these structures upon postural tone is produced ultimately through both the somatic and sympathetic efferent connexions to skeletal muscle. In other words, there are two final common pathways to each muscle. The excitatory impulses emerging through the somatic motor pathway all give rise to a contraction of the muscle or to contractile tone. The effect of the excitatory impulses emerging through the sympathetic rami communicantes is to fix the existing length of the

muscle (plastic tone). It is obvious that this is a primary subdivision of postural tone according to the properties subserved by the two efferent connexions of skeletal muscle. The sources of the impulses emerging through each pathway are numerous in each case, as already mentioned. Both connexions are in fact final common pathways in the sense of the term employed by Sherrington.

**TECHNIQUE OF EXPERIMENTS IN WHICH THE DECEREBRATE ANIMAL WAS EMPLOYED TO DETERMINE THE EFFECT OF REMOVING THE SYMPATHETIC INNERVATION OF SKELETAL MUSCLE.**

The negative and inconsistent results obtained by previous investigators employing the decerebrate preparation to determine the function of the sympathetic innervation of skeletal muscle call for comment. The following points appear to have been of importance in leading to the success of the experiments of this kind in the hands of Dr. Royle.

*The Interval between the Removal of the Sympathetic Cord and the Operation of Decerebration:*

In our experiments on goats the lumbar portion of the sympathetic trunk was removed from one hind limb. This was done as a preliminary procedure. Then, at a variable period after this operation decerebration was performed. In our first series the interval between the two operations varied from seven to seventy-three days. The best contrast between the hind limbs on the operated (left) and unoperated (right) side was seen in the animal in which the interval between the operations had been longest. In this animal extension of the left limb was easily overcome in contrast to the opposite limb. When not handled with the animal lying in the supine position, so fixed as to eliminate the disturbing influences, vestibular and cervical (such as Magnus and de Kleijn have described), the left limb rapidly fell from its temporary position of extension to a passive posture of semiflexion. In this stage of relaxation the "lengthening and shortening reactions" were absent.

These effects depend upon the loss of plastic tone. The comparative ease in performing passive flexion of the extended limb is due to the fact that contractile tone, which is responsible for thus imposing this position, alone has to be overcome to alter the position. On the intact side, while contractile tone is responsible for the position of extension, it is assisted by plastic tone, which tends to fix the length of the muscles necessary to maintain this position. When contractile tone is overcome on the partially denervated (that is, deprived of sympathetic nerves) side no further resistance to movement is offered. On the opposite side, though resistance suddenly gives way when reflex shortening of the extensor muscles (that is, contractile tone) is overcome, some degree of resistance to passive flexion is still maintained, because plastic tone still persists. As Walshe has pointed out, this phenomenon has its counterpart in the clasp-knife effect of decerebrate rigidity.

Decerebrate rigidity is due to the presence of an exaggerated degree of both contractile and plastic tone. The extended position imposed by contractile tone (as the result of the

When the limb was passively extended or relaxed spontaneously it would fall into a semiflexed position determined by gravity and the length of the fibrous tissues contained within the limb. If the knee-joint were now passively flexed or extended the leg would resume its original posture. In other words, a passive posture characterized the limb instead of the ability to occupy active postures, which is the property of the normal musculature in the decerebrate preparation. For the "shortening and lengthening reactions" are no longer exhibited—that is, plastic tone is absent.

Unquestionably these three manifestations of the loss of plastic tone are not so clearly exhibited when the interval between lumbar sympathectomy and decerebration is short—for example, when decerebration is performed on the same day as that on which the lumbar sympathetic trunk is removed. I have records of three decerebrate preparations that exhibited the "lengthening and shortening reactions" in this way when both procedures were carried out on the same day. In each of these, however, the resistance to passive flexion and the tendency for the maintenance of the extended position were definitely less than on the control side.

The explanation of the progressive loss of plastic tone may be that this property of skeletal muscle is less dependent upon impulses emerging from the central nervous system than is contractile tone. In this respect skeletal muscle would resemble, to a certain degree, smooth muscle, the tone of which is not absolutely dependent upon its nerve supply. However, there are difficulties in accepting this analogy as an adequate explanation, because recovery in the tone of involuntary muscle occurs as time advances following denervation. But in view of the fact that only some muscle fibres receive sympathetic nerve fibres and are therefore alone responsible for the property of plastic tone (see the first lecture), it is feasible that these denervated "fixing" fibres slowly lose this property following sympathetic denervation, so differing from the neighbouring "movement fibres," which are absolutely dependent for their property of contractile tone upon the intactness of the central connexions of the somatic nerve fibres that supply them. Moreover, in the lumbar operation so far employed, it is necessary to bear in mind that all the sympathetic ganglia from which the grey rami to the lower limb arise are not removed, though efferent impulses from the spinal cord to them are eliminated. This fact may perhaps in some measure account for the progressive loss of plastic tone. However, the whole problem of the determination of the time necessary to produce the complete effect after sympathetic denervation is now being investigated. It can best be solved by studying the effects of the operation in the chronic decerebrate animal described by Bazett and Penfield.<sup>12</sup> Delaying the operation of decerebration until a long interval after the removal of the sympathetic cord disposes of certain claims that have been made in the attempt to explain the changes revealed after sympathetic denervation. In the first instance diminution in tone cannot be ascribed to sensory inhibition due to the wound inflicted in performing the operation of sympathectomy,<sup>13</sup> for ample time is provided to allow healing of the wound to occur. Nor are the changes due to vaso-dilatation, because the diminution in tone persists, or even increases in degree, although the vasomotor changes are a maximum immediately after the operation.

Sympathetic ramisection in human patients affords similar results in this direction; for the loss of plastic tone has persisted for twelve months in the case of Royle's first patient subjected to the operation, although obvious vasomotor changes were present only in the first few weeks. In other patients the circulatory disturbance has been of greater duration: but it had a general tendency to be reduced in degree, while the loss of plastic tone was still apparent. Some of the effects of sympathetic ramisection upon tone may, however, be due to the attendant increase of blood supply to the limb. I refer to its effect upon contractile tone. Dr. Royle has noticed, for instance, that cold has less effect in increasing contractile tone in the limb of a spastic paraplegic which has been subjected to operation than in the limb of the opposite side. As a result of vaso-constriction the limbs of the spastic paraplegic are

FIG. 6.—Decerebrate goat with both fore limbs and the right hind limb rigidly extended. The left hind limb (deprived of its sympathetic innervation) is relaxed. Head and neck fixed to prevent Magnus and de Kleijn phenomena. Note the force necessary to bend the right hind limb.

selective reflex shortening of the extensor muscles) is rigidly maintained by the fixation of the extensor muscles in their shortened state by plastic tone. In the absence of plastic tone this rigid fixation is no longer apparent, and the limb fails to maintain the extended posture (Fig. 6) once the reflex shortening of the extensors dependent upon impulses emerging through the intact medullated somatic nerves ceases. The active posture of extension is now no longer maintained.

invariably colder than normal. The advent of vaso-dilatation (with an attendant increase in temperature of the limb) lessens the degree of contractile tone. This reduction is greater immediately after the operation than it is subsequently, for the vasomotor changes become less marked as time proceeds. But the reduction in plastic tone progresses in the opposite direction.

#### *The Method of Examination of the Animal.*

After removal of the sympathetic innervation of one limb the otherwise intact goat can walk, and run, in the normal manner. The characteristic change produced by the operation is revealed, however, if the animal is placed in the supine position with its head held rigidly in the mid-line. All limbs take up an extended posture under these conditions, but, as Dr. Royle has shown, when the cause for alarm is removed by gentle handling of the animal—for fear excites the defensive reaction of extension—the lower limb of the operated side falls from the extended position into a passive posture determined by mechanical factors. This method of examination for changes in the postural tone of the limb was adopted with advantage for the decerebrate preparation. The goat is placed in the supine position in a cradle and the head is held firmly in the median line, or the animal is first encased in a leather jacket which fits round the trunk and neck, and then placed in the cradle. In this way the effects of the tonic labyrinthine and neck reflexes of Magnus and de Kleijn are excluded. Under these conditions the typical extensor posture, as already explained, is assumed by all four limbs. But after a short period the limb which has been deprived of its sympathetic innervation falls under the action of gravity to a passive posture of abduction and semiflexion.

By this method of examination any defect in the maintenance of posture is readily indicated by failure of the skeletal musculature to support the weight of the limb. This is a matter of importance, for efforts to test for diminution of tone by passive movement set up a reflex spasm of the musculature of the limb which is evidence of the excitability of the nervous connexions responsible for contractile tonus. Clinicians are familiar with this observation. For spastic muscles may before palpation show no evidence of an increased degree of contraction; but a reflex tonic contraction is set up immediately passive movement is attempted. In the first phase the posture is maintained predominantly by plastic tone. After examination of the limb is commenced increased contractile tone is superadded. Obviously the effect of passive movement will be to obscure any diminution in the degree of plastic tone. Nevertheless, passive movement overcomes contractile tone alone more easily than contractile and plastic tone combined.

The results of my experiments on the wings of birds are so important and illuminating that, at the risk of making this account unduly long, I must make some reference to them.

## TUBERCULOSIS INCIDENCE AND CLIMATE IN INDIA:

### RAINFALL AND WET WINDS.

BY

SIR LEONARD ROGERS, C.I.E., M.D., F.R.C.P.,  
F.R.S., LIEUT.-COLONEL, I.M.S. (RET.).

In 1923 I published maps<sup>1</sup> showing a close world-wide relation between high rainfall and high leprosy incidence, and also demonstrated the same point in detail for India by means of the leprosy census figures and a study of the rainfall records of two thousand stations in that country, the only exception being that the disease appears to have spread from the wet Bombay coast into the comparatively dry Deccan along the oldest known trade routes in India. I also collected data regarding the incidence of tuberculosis in a number of tropical countries, but found the relation to rainfall to be less striking than in the case of leprosy, while M. Kerandel<sup>2</sup> has recently come to a very similar

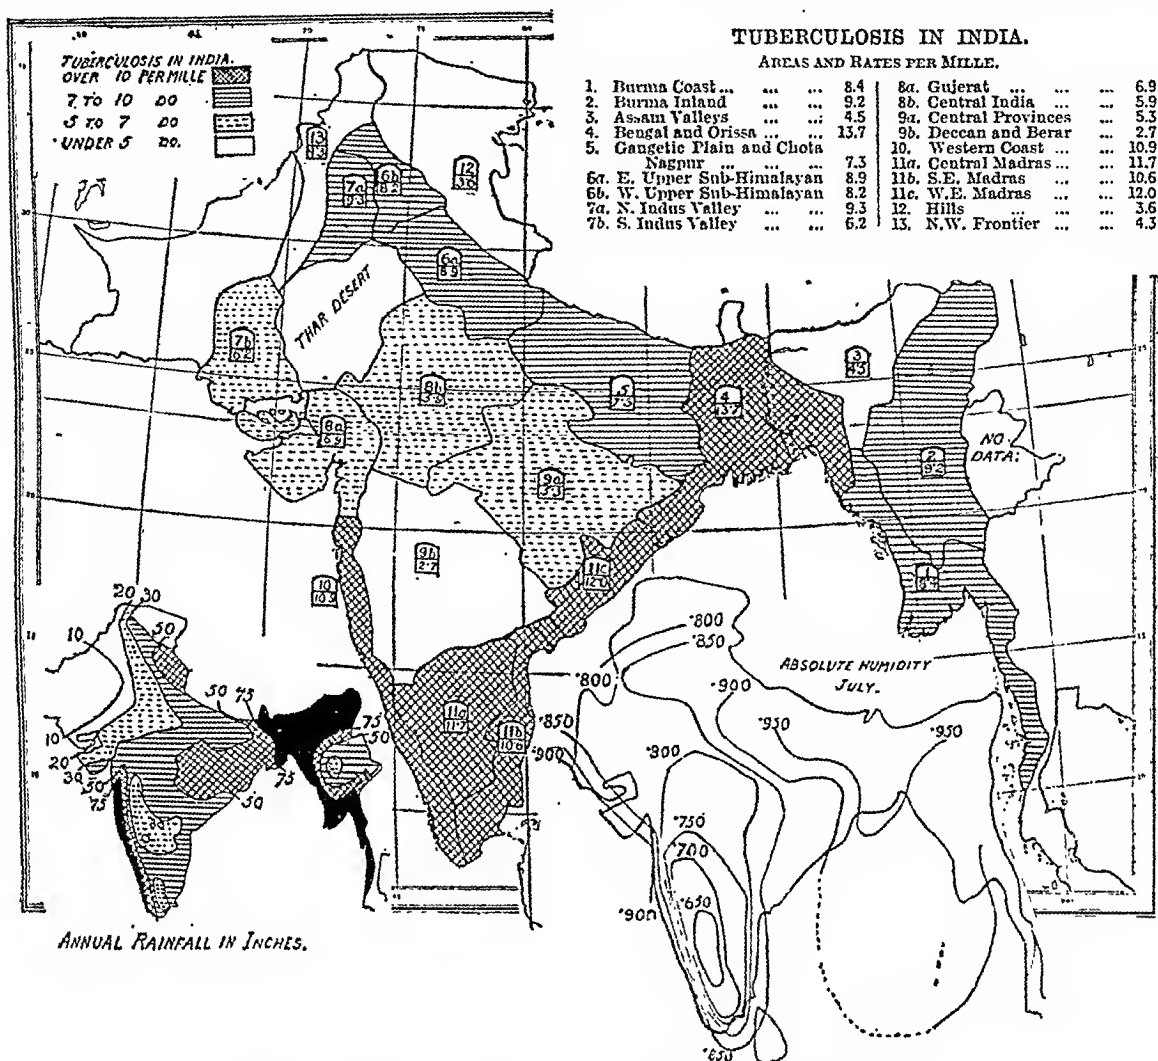

conclusion from a study of tuberculosis in the French colonies, as, although the hot, dry climate of the Sudan is unfavourable to the development of tuberculosis, he found no general close relationship between climate and the incidence of the disease. This is largely due to the variations in the type of the disease with the degree of tuberculinization of races. Those recently infected, such as in some areas of Oceania and tropical Africa, show the acute rapidly fatal infantile type with a low percentage of positive tuberculin reactions; while in Indo-China, with evidence of centuries of tuberculosis, the more chronic European type with a fairly high percentage of tuberculin reactions is found. This is also the case in India, where I met with many cases of fibroid phthisis in the post-mortem room, in spite of the disease running a somewhat more rapid course in that hot climate than in Great Britain, as A. Powell<sup>3</sup> also found in Bombay.

India, therefore, presents very favourable conditions for a study of the incidence of tuberculosis in relation to climatic conditions, for this large country shows extremes of rainfall from 500 inches on the south side of the Khasia Hills of Assam to 5 or less in North-western India. It also affords splendid meteorological records, and reliable data regarding the incidence of phthisis in the jail population; these institutions are under Indian Medical Service officers, and necropsies are regularly performed on fatal cases, and the actual figures and the rates per mille are published in the annual reports of the Sanitary Commissioner with the Government of India. For the purposes of the present inquiry I have worked out the phthisis rates of all the jails for ten consecutive years; they total over one million persons. I have selected a decade subsequent to the 1891-92 influenza pandemic, and prior to that of 1918, which so greatly increased deaths from tuberculosis in India. The yearly figures for each of the areas into which India has been divided in relation to the climatic features for the purposes of the Sanitary Commissioner's report, show such closely similar figures year by year that they are clearly sufficient for the purpose in view.

The distribution of pulmonary tuberculosis in the Indian jails thus obtained is shown in rates per mille of the jail population in Map 1, the crossed lines representing over 10 per mille, the single horizontal lines 7 to 10, the dotted areas 5 to 7, and the unshaded parts under 5 per mille, the actual figures being entered in the squares in each area, with the number of the area above it. The left-hand small inset map shows the annual rainfall distribution of India, while that on the right gives the absolute humidity, or mean daily aqueous vapour pressure, of July at the height of the south-west monsoon rainy season; this allows ready comparison of the high and low tubercle areas with the rainfall and humidity, which may now be considered. The numbers in parentheses refer to those of the different areas for convenience of reference.

#### *Relation of Tuberculosis to Rainfall.*

The first point to be noted is the general relation, with certain exceptions, of high tubercle rates and high rainfall, as shown by the very high tubercle rate of 13.7 in Bengal with the very heavy rainfall of over 75 inches, and of 10.9 in the West Coast area (10) with 100 inches of rain annually. Connecting these two areas is the eastern Madras coast (11b and 11c) with 10.6 to 12 per mille, and an annual rainfall of 30 to 50 or more inches; here it is important to note that, although the total rainfall of the Madras coast is less than that of Bengal and the western coast, it is distributed over seven or eight months of the year, instead of being limited to the four monsoon months from the middle of June to the middle of October, as in most parts of India, for the Madras coast gets part of the south-west monsoon, followed by the exclusive influence of the north-east monsoon from October to December, so that its climate is particularly humid. Its relative and absolute mean annual humidity is, in fact, greater than that of any other part of India except Lower Burma. On the other hand, Central Madras (11a) has the comparatively low annual rainfall of 20 to 30 inches, but the high tubercle rate of 11.7 per mille. This exception requires explanation; this area has a low leprosy incidence. The Andaman

MAP 1.—The incidence of tuberculosis in India in relation to rainfall and humidity.

Islands, to the south-west of Burma (see inset of Map 2) have an annual rainfall of 114 inches and a very high degree of humidity, and in accordance with this its large jails show the high tubercle rate of 10.7 per mille.

The moderately high tubercle incidence of 7 to 10 per mille occurs in two distinct areas, one on either side of the very tuberculous Bengal area. To the east is Burma, with a very high rainfall (except in a central inland area which has a comparatively low annual rainfall); but the whole province has a high degree of absolute humidity, both during the monsoon months (see right-hand inset of Map 1) and for the whole year, as in the case of Madras. To the west of Bengal the moderately high tubercle area extends throughout the sub-Himalayan divisions of Bihar, the United Provinces, and the Punjab (5 and 6) as far as the main Indus River; this in spite of the fact that the rainfall rapidly decreases in the south-western portions of the Punjab to below 30 inches annually. Here, once more, on turning to the humidity we find that during the monsoon months the mean daily aqueous vapour pressure reaches as high as 0.850 in July throughout the sub-Himalayan area up to the Indus—that is, just as far as the moderately high tubercle incidence extends (see right inset of Map 1). So that here, as in Central Burma, a high degree of humidity is carried by the monsoon current considerably beyond the region in which a high rainfall is precipitated. We may, therefore, conclude that every part of India with tubercle rates of over 7 per mille has a humid climate during the rainy seasons, with the partial exception of

Madras (11a), which is, however, influenced by the north-east monsoon during the autumn months; in the case of the latter, however, and of the south-west of the Punjab, the annual rainfall is comparatively low.

The moderately low tubercle rate of 5 to 7 per mille, which is below the average rate for the whole country, forms a well defined belt stretching right across Central India to the south of the sub-Himalayan area (5, 6a, and 6b), and includes from left to right in Map 1 Sind (7b), Gujerat (8a), Eastern Rajputana and Central India (8b), and the Central Provinces (9a), and all but the easterly part of the Central Provinces have a low or moderate rainfall limited to the period of the south-west monsoon.

The lowest tubercle rates of under 5 per mille, or less than half those of the highest areas, are found in four areas presenting very different climatological features, and are therefore of especial interest, since they cannot be fully explained in relation to rainfall and humidity alone. The lowest rate is in the extensive area of the Deccan and Berar (9b) with only 2.7 per mille, or one-fourth of the high areas. It is noteworthy also that this division is immediately contiguous with the highly tuberculous West Coast area (10), from which it is separated by the Western Ghats mountains. This is shown in Map 2, in which the dotted portions represent hills between 2,000 and 3,000 feet, those marked by single horizontal lines hills of 6,000 feet, and the crossed lines hills upwards of 6,000 feet; these hills cut off the south-west monsoon to such an extent that the coastal rainfall of upwards of 100 inches is reduced

to under 30 inches in much of the Deccan, and in a small area to under 20 inches annually (see left inset of Map 1). On the south the Deccan borders on Southern Madras, which receives the full influence of the autumn north-east monsoon, which does not affect the Deccan itself. Further, the absolute humidity during the monsoon months is the lowest in India in the dry Deccan area, as shown in the right inset of Map 1; the mean daily aqueous vapour pressure, or absolute humidity, is as low as 0.700 to 0.650 in this area during the height of the monsoon in July; this is in striking contrast with the relation between high absolute humidity and high tubercle incidence already shown. Similar conditions obtain in the North-west Frontier Province (13), which has a very low rainfall and comparatively low humidity because the south-west monsoon current of the Bay of Bengal does not reach quite as far as this area, the northern portion of which is protected from the damp monsoon currents by the Salt Hills, represented by the small shaded area to the east of the Upper Indus in Map 2; this area has the next lowest tubercle rate for the plains of India (4.3 per mille).

The two remaining areas of low tubercle prevalence present very different features from those just dealt with. Area 12 includes the Himalayan hill stations, together with a small jail in the Assam Khasia Hills; the rate per mille is only 3.6, and is lower than any except that of the Deccan. The Himalayas and Khasia Hills have high rainfalls and great humidity during the monsoon months, but a much lower temperature than the plains (they are at an elevation of from 5,000 to 8,000 feet); so some other factor must be sought for to explain their low tubercle rates. The remaining area of the Surma and Brahmaputra valleys of Assam (the Khasia Hills jail being included in area 12 just dealt with) has an exceptionally heavy rainfall of over 75 inches annually, together with a most humid climate without even the coolness of the hill area; yet the tubercle rate was only 4.5 per mille, the Surma valley rate (to the south of the Khasia Hills, and continuous with Eastern Bengal) being as low as the Brahmaputra valley one. This condition of affairs cannot be explained in relation to rainfall and humidity, any more than the high rate in the comparatively dry Central Madras area. Some other influencing factor must, therefore, be sought. I turned to the Climatological Atlas of India of the Meteorological Department, which gives maps illustrating the monthly and annual rainfall, clouds, relative and absolute humidity, temperature, including its diurnal variations, and the pressure and air movements. All of these data I have studied in relation to tubercle distribution in India, with the result that the key to the problem appears to reside in the monsoon barometric pressures and air movements, that of the middle of the rainy season in the month of August being shown in Map 2, while the small map illustrates the same data in December during the north-east monsoon.

#### *The Pressure and Air Currents in India in Relation to Tuberculosis.*

The annual rainfall of India is very largely precipitated during the four south-west monsoon months, when the barometric pressure is lowest in the north of India. The Madras Presidency is an exception, inasmuch as it receives much of its rain in the last three months of the year during the north-east monsoon, when the more northerly parts of India have a high pressure and no rain. In the maps the arrows represent the direction of the monsoon currents, their length indicates the steadiness of the wind, and the number of the feathers its velocity, increasing from two to over twenty miles an hour with the increase in the number of the feathers. About the middle of June the south-west monsoon strikes the west coast of India, much rain being precipitated on the coast and on the Western Ghats, and but little in the Deccan to the east of the mountains, while north of this range a weaker part of the current passes through Gujarat to Central India, and is broken up by the hills of this area, to which it gives only moderate rainfall. To the south of India the monsoon enters the Bay of Bengal, furnishing abundant rain to the Andaman Isles and to the Burma coast and the Irrawaddy valley; it then passes up along the Orissa and Arrakan coasts, to enter Lower

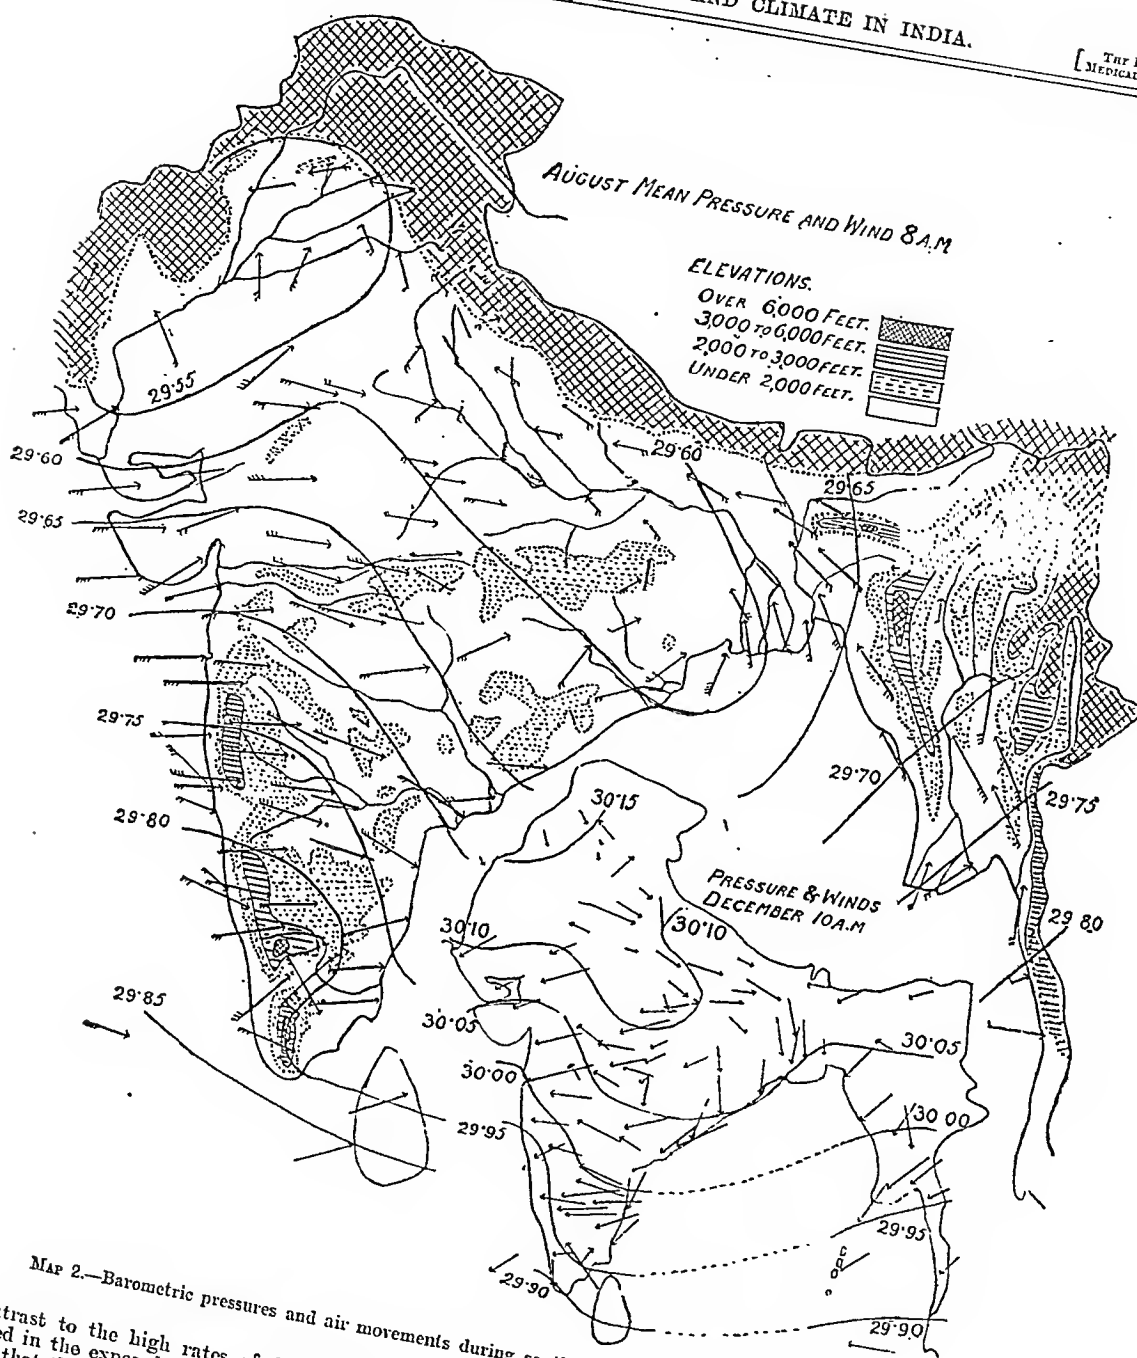

Bengal at the delta of the Ganges and Brahmaputra rivers; meeting the lofty Himalayan barrier, it turns north-west up the Ganges valley in the sub-Himalayan region as far as the Upper Indus valley, to disappear just to the east of the North-west Frontier Province. This is shown by the arrows in the larger map.<sup>1</sup> In the smaller map of the north-east monsoon in December it will be observed that all the winds are dry land winds with the exception of Southern India, over which the humid currents from the Bay of Bengal blow across the east coast (11b and 11c) and the southern central area of high tubercle prevalence (11a), as shown in the inset of Map 2.

#### *Relation of Rain-bearing Currents to Tubercle Incidence.*

It will at once be evident that the highest tubercle incidence in Bengal and in the west coast area corresponds with the strongest south-west monsoon currents, and that of the Madras Presidency to those of the north-east monsoon, while the coast areas also have humid afternoon sea breezes even in the rainless periods. (The conditions at 8 a.m. are shown in Map 2 (larger map); those at 10 a.m. are shown in the smaller map.) The moderately high tubercle areas of Burma and the sub-Himalayan districts also feel the full effects of the monsoon currents; the moderately low areas of Central India have weaker monsoon currents, and also receive a good deal of protection from their low mountain ranges and hills, while the lowest tubercle area in the Deccan is protected both from much rain, and still more from the rain-bearing monsoon currents, by the Western Ghat mountains.

Turning now to the puzzling conditions presented by Assam, with high rainfall and humidity but low tubercle rate, we find that the short Surma valley to the south of the Khasia Hills is completely protected from the main monsoon winds by the Arrakan and Tipperah Hills to its south, over which the rain-bearing currents pass to strike the top of the southern face of the Khasia Hills, rising nearly vertically to 4,000 feet at Cherrapunji, which records the highest known rainfall of the world, of 300 to 500 inches annually. Yet the short arrow shown in this valley in Map 2 indicates only an unsteady slight wind blowing in a westerly direction from the Manipur Hills to its east, and south-west monsoon winds do not enter the valley. Still more protected from the monsoon currents is the narrow Brahmaputra valley between the Garo, Khasia, and Naga Hills, running up to 4,000 to 6,000 feet to its south, and the mighty still largely unexplored Himalayas to its north. I can find no other explanation of the very low tubercle rate of the Assam valleys than this protection by mountains from the rain-bearing winds, in spite of the heavy rainfall, as the Sylhet district of the Surma valley has a dense population, which has for centuries been in close communication with highly tuberculous Bengal.

There remains to be explained the exception in the opposite direction—namely, the high tubercle rate with a low rainfall in Central Madras (11a), for although this area is exposed to the autumn north-east monsoon currents, it receives, as compared with the east coast area (11b), less rain from them. On examining the height of the Western Ghat mountains, as shown by the shading in Map 2, it will be observed that there are three portions running up to between 3,000 and 6,000 feet or more in height, separated by two gaps of low hills. In the southern of these (the Palghat gap) they do not even reach 2,000 feet, while the more northerly gap shows only a very narrow belt just over 2,000 feet. Both of the arrows shown in the lower gap point to dots, which represent the positions of the Coimbatore and the Salem jails, while that in the more northerly gap points to Bellary: the only three jails furnishing the tubercle figures of Central Madras (11a), and each is situated in the direct path of the humid monsoon winds, after they have deposited most of their rain on the Ghats. A little below the middle of the most northerly of the three high portions of the Western Ghats is another arrow pointing to a dot just to the east of this broad and high mountain barrier; it represents Bijapur, which is only a little more than a hundred miles north of Bellary, but in the dry sheltered Deccan, and has a very low tubercle rate.

MAP 2.—Barometric pressures and air movements during south-west and north-east monsoons.

In marked contrast to the high rates of Coimbatore and Bellary, situated in the exposed gaps in the mountains. Thus we find that the two striking exceptions to the rule of high rainfall and humidity and high tubercle incidence, and vice versa, are both readily explainable on the ground that exposure to humid monsoon winds, apart from actual high rainfall, favours tubercle, as in Central Madras, and that shelter from such winds, in spite of very heavy rain, as in Assam, lessens the incidence of the disease. The low tubercle rate in the hill jails is also explained by the fact that most of them are protected from the direct influence of the monsoon currents by higher hills to the south of them in addition to a cool climate.

#### Conclusions.

The direction, steadiness, and strength of the rain-bearing winds appear to be the most important factors,

in addition to high rainfall and absolute humidity, in influencing the prevalence of pulmonary tuberculosis in Indian jails.

These observations are in accordance with the well known observations of Dr. W. Gordon of Exeter<sup>1</sup> on the relation between exposure to humid winds in Devonshire and the incidence of phthisis, and afford them strong support on a very large scale, since the monsoon-influenced Gauges and Upper Indus valleys extend over 1,400 miles.

Their bearing on the choice of a residence for an actual or potential phthisical patient, and on the choice of sites for sanatoriums, is obvious.

## SOME AFFECTIONS OF EPIPHYSES.\*

BY

H. A. T. FAIRBANK, D.S.O., M.S., F.R.C.S.,  
SENIOR ORTHOPAEDIC SURGEON, KING'S COLLEGE HOSPITAL; SURGEON  
TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

I PROPOSE to begin my address on some affections of epiphyses with an account of three traumatic cases, all boys of 16 years of age, and all sent up from the same school by the same doctor, Dr. A. M. Ansler. These cases seem to me of importance, since the lesion in each case is easily missed unless perfect radiograms are available. They emphasize the importance of x-ray examinations in all cases, however trivial, in which it is possible that a lesion of a bone has occurred.

The first is an early separation of the femoral head—that is, an early adolescent coxa vara. A common history in such a case is that of a series of two or three minor accidents, such as falls in the football field, leading in each case to a limp, which finally becomes persistent and increases. It is of the greatest importance to recognize this condition in its early stages and to take steps to prevent its increase, but it is rare, in my experience, for the surgeon to see a case before considerable displacement has occurred.

## CASE I.

A boy, aged 16, in September, 1922, fell on the right knee without hurting himself much, and on return to school he fell twice in the football field and hurt his right hip; after the second fall the hip continued to give pain; the pain was in the groin and on the outer side of the hip; a trip increased the pain. When seen, a month or so later, he was limping and the pain was increased by walking or even moving the hip when sitting.

On examination the hip showed no deformity, but there was slight fullness in the groin with tenderness here and over the trochanter. Abduction and internal rotation were limited; flexion and extension were only slightly limited. Shortening amounted to three-eighths of an inch, and there was slight wasting. There was pain on jarring the heel, and also, though less marked, on jarring the trochanter. The skiagram shows widening of the epiphyseal line and definite, though slight, depression of the right femoral head on the neck. Weight extension was applied and the leg put up in abduction and internal rotation, these two being increased day by day till extreme limits were reached, when the limb was fixed in plaster-of-Paris. It was hoped that the small amount of displacement of the head of the femur might be corrected, but unfortunately this was not achieved. The plaster cast was left on for three months and a walking calliper worn for a year. No increase of the deformity occurred.

## CASE II.

The next case, also a boy aged 16, after falling once or twice in the football field without hurting himself particularly, noticed pain in the left hip while running, and found he could not kick with the left foot. After this game he played twice only, as on each occasion he had experienced pain after five minutes' play. In an hour or so the pain had disappeared, and he only felt the hip on twisting or jumping. Walking caused no pain and there was no limp.

Physical examination was negative when seen three weeks after the onset, but some thickening of the trochanter had been noticed, and this had gone down with massage. A radiogram showed partial separation of the great trochanter, the space at the site of the epiphyseal line of the great trochanter being definitely wider on the left than on the right. Abstinence from all games for a couple of months or so effected a cure.

Separation of this epiphysis is usually complete and the result of direct violence. Although it might be expected that muscular action would be a not uncommon cause, the lesion usually results from direct trauma. A few cases due to muscular contraction have been recorded, but they are not very convincing. The commonest period for its occurrence is from the thirteenth to the sixteenth years. The displacement is usually not great and the diagnosis is difficult. In the recorded cases, mostly reported some years ago, a surprising number seem to have been complicated by infection of the haematoma. Of 11 cases (Poland) 6 were followed by suppuration and 5 of these died. Some seem to have been primarily infective osteomyelitis with secondary separation of the epiphysis.

## CASE III.

This patient showed an even rarer injury. A lad of nearly 17 complained that while playing football and running all out the left hip suddenly hurt him and gave way so that he fell, another boy falling over him. He finished the game, but with pain. When seen five days later he said he had only a little pain on walking, but any attempt at running caused considerable pain. He did not

\* Presidential Address to the Section of Orthopaedics of the Royal Society of Medicine, October 7th, 1921.

limp and no physical signs were present. The radiogram shows separation of the epiphysis of the anterior inferior iliac spine, the centre for which appears at the fifteenth year or later. Games were forbidden for a few weeks.

This would seem to be a very rare injury. Poland gives a few cases in his wonderful treatise on epiphyses. This injury usually gives rise to greater disability than in my case, the hip being flexed, and it is difficult or impossible for the patient to extend the hip and the knee. Soft crepitus may be obtained. The avulsion usually occurs in sprinters in the violent effort of starting a race. The reflected head of the rectus, which is not torn, prevents great displacement.

We may now pass on to consider the tubercle of the tibia. While there is some doubt as to whether the so-called Schlatter's disease is necessarily traumatic in origin, though certainly aggravated and kept up by the pull of the ligamentum patellae, there is no doubt that all types of cases are met with, from the complete traumatic avulsion of the tubercle to the case where no displacement is present and trauma seems to play no part in the onset.

The following case is at one end of the series, and is, I think, exceptional in that the plane of fracture passed up through the epiphysis into the joint, the anterior part of the articular surface of the tibia being displaced. A boy of 14, while attempting to jump a rope, felt something give in the knee as he took off with the left foot. A skiagram showed the displaced fragment to consist of the anterior third of the articular surface of the tibia as well as the tubercle. At operation the fragment was forced back into place and fixed there with a beef-bone screw, the drill hole being tapped to fit the screw. The result was entirely satisfactory. In another case, that of a boy aged 14 who had had symptoms for four months, a radiogram of the knee showed the typical fluffy condition of the tongue-like process forming the tubercle and of the bone beneath it, with some irregularity of the intervening cartilage. Abstinence from all games for a time has been sufficient in most of my cases to relieve symptoms, though the possibility of a recurrence cannot be said to have disappeared till fusion of the tubercle with the shaft of the bone has occurred.

I now want to refer to a less known, though not less common, affection of a similar nature—namely, osteochondritis of the heel epiphysis. This, like the affection preceding it, and that which is to follow, is an affection of an epiphysis to which a strong tendon is attached, so that trauma would naturally be expected to play a part in the causation. While in "Schlatter's knee" trauma plays a more prominent part than in the others, it is difficult to get away from the impression that a mild infection must play a part in all, and more particularly in the cases of the heel and of the navicular tubercle to be mentioned later. This infection and resulting inflammatory change is necessarily aggravated by the pull of the tendon attached to the affected epiphysis, and there is no doubt that violent exercise does increase the symptoms and that rest is followed by partial or complete relief. While in the case of the tibial tubercle, as already mentioned, definite traumatic displacement, partial or complete, does occur as a result of violent action of the quadriceps, I know of no convincing case of separation of the epiphysis of the os calcis, nor of the navicular tubercle, though I have one case to show you of fracture of the os tibiale externum. The vast majority, if not all the cases of supposed tearing off of the navicular tubercle, are really explained by the presence of a separate centre of ossification in this tubercle—the so-called os tibiale externum. Although in the affection under consideration an infective focus is probably present, it is not easy to find as a rule. More than one writer has drawn attention to the similarity of these affections to pseudo-coxalgia and to Köhler's disease. In the case of the former, the femoral head being an epiphysis subject to very considerable strain, the similarity is striking, but in Köhler's disease the radiographic similarity between the affections is not nearly so convincing, nor in this case is the bone, the tarsal scaphoid as a whole, subject to an unusual amount of strain.

Osteochondritis of the heel affects boys rather more frequently than girls and is more commonly bilateral than

unilateral, the left heel being affected in my small series of fourteen cases much more frequently than the right. The ages of the patients varied from 8½ to 15 years. In only one, in whom the affection was started by a jumping competition, was anything in the way of unusual trauma discovered. The diagnosis depends on local pain and tenderness and the x-ray changes. The pain is definitely in the heel and not beneath it, and is aggravated by violent exercise; the tenderness is on one or both sides, at the margin of the epiphyseal line, and occasionally at the back of the heel; swelling may be present, but is often absent. Flat-foot may be present, and occasionally there is some shortening of the calf muscles. Radiograms show a fluffy, caten-out, or fragmented epiphysis with unusual irregularity of the adjacent posterior surface of the body of the os calcis. Great irregularity of this surface has been met with—in a large number of radiograms specially examined—only when symptoms of the disease had been present at some time or other in the case. It must be remembered that the epiphysis may ossify by more than one centre, and, as in the case of Schlatter's disease, radiograms must be examined in conjunction with the clinical evidence, unless the changes are very marked or unilateral. This is apt to be a chronic complaint, and while only occasionally is complete rest, even in plaster, indicated, abstinence from all violent exercise may have to be enforced for several months. Cure, as in the case of the tibial tubercle, takes place when fusion of the epiphysis with the rest of the bone occurs, but fortunately symptoms may subside long before this. The later the affection occurs the better, therefore, the prognosis. One case of a relapse after an interval of two years was met with. I will now show you radiograms of three cases:

(a) A girl, aged 8½, with pain on the inner side of the left heel of some months' duration.

(b) A boy, aged 12, with pain in the right heel for two months. Irregularity of the subepiphyseal surface of the body of the bone is well marked. Later the other heel developed symptoms.

(c) A girl, aged 13, with pain in the right heel of two months' duration. She complains of pain and tenderness after running or jumping. Flat-foot is present. The radiogram shows fragmented, fluffy epiphysis on the right side.

Precisely similar in nature is an affection of the tubercle of the tarsal scaphoid, to which is attached, of course, the tibialis posticus tendon. I have seen both the scaphoid and the os calcis affected in the same foot. It may be as well to say that I am not speaking of Köhler's disease, or isolated disease of the navicular, but of an entirely different condition. Here we are dealing with an affection of the navicular tubercle only, and not of the whole bone. A child or adolescent complains of painful flat-foot, the navicular tubercle being unusually prominent, painful, and tender, the tenderness being usually on the posterior aspect of the process rather than on the tip, which might well be rubbed by the boots. An interesting fact, and one I have not seen mentioned, is that almost invariably a separate centre of ossification is present in these cases for this tubercle—the so-called os tibiale externum. In 11 cases, with bilateral symptoms in 7, making 18 feet in all, one or more centres of ossification for the tubercle were present in 13, in 2 others there is a questionably minute fragment of bone, while in one double case radiograms are not available to decide the point. The presence of an epiphysis at this point makes the anatomical conditions similar to those in the heel and the tibial tubercle. In only one or two has there been any suggestion of fluffiness of this epiphysis, if we may so call it. Girls are nearly twice as commonly affected as boys, in contrast to the heel cases, the ages varying from 9½ to 16 years in my series, the girls being rather younger. The sides are equally affected. The undue prominence of the tubercle, which is of course extremely common in painless flat-feet in children, is often equally great on the two sides, even though signs and symptoms are unilateral, while the os tibiale externum is usually bilateral. It is not known, so far as I am aware, what is the usual fate of this bone. It certainly may remain as a separate fragment throughout life, while the appearances seen in some feet strongly suggest that a separate bone had been present and had united to the navicular. The feet are almost invariably

flat, and in rare cases the calf is contracted. These cases are not quite so obstinate as the heel cases. Treatment should aim at supporting the arches and ordering a varying degree of rest according to the severity of the symptoms. Plaster may be advisable for a time. Exercises, etc., for the cure of the flat-foot must be delayed till all pain and tenderness have disappeared. I will show you radiograms of three typical examples:

(a) Boy, aged 13, with local pain and swelling for ten days only of the left navicular tubercle. Slight valgus was present; os tibiale externum on both sides, but larger on the left.

(b) Girl, aged 14, with bilateral flat-foot. Prominent navicular tubercle on the left. Tender at back. Pain on walking much for some weeks. There is some irregularity of the os tibiale externum on the left.

(c) Boy, aged 13, with prominence of both navicular tubercles, but only the right was tender at back. Three fragments of bone are seen in the region of the navicular tubercle.

Another radiogram is from a woman of 51 who had turned her ankle in 1923 and had had pain in the foot ever since. An os tibiale externum is present on both sides, but on the right the bone is apparently fractured. I have not met with a similar radiogram. A month's rest was followed by return of pain as soon as she got up again. Removal of the bone was recommended.

I now want to show you a radiogram in which is seen a separate centre of ossification for the internal malleolus. This is a very rare condition and apparently unknown to many anatomists. Curiously enough I have met with 5 cases: in 3 the condition was bilateral, in 2 unilateral; 4 had severe flat-foot with pain, one also having peroneal spasm: the condition was only revealed by routine x-ray examination. Only 2 showed any local signs, and in these the tenderness, and in one also some swelling behind and below the malleolus, rather suggested teno-synovitis of the tibialis posticus tendon, but this could not be connected, directly at any rate, with the presence of this separate epiphysis. The radiogram shown is from a girl aged 10 who complained of pain and flat-foot. She had been kicked on the right ankle five months previously, and when seen there was a puffy, tender swelling below the internal malleolus on this side. The separate epiphysis is bilateral. It is extremely unlikely that the existence of this epiphysis had any relation to the symptoms.

Lastly I show you a case of dislocation of the elbow with separation of the epiphysis of the internal epicondyle. During reduction by the doctor, the separated internal epicondyle was by some chance caught between the humerus and ulna. At operation we were able to free the detached piece of bone, and, after drilling it, to stitch it back somewhere near its correct position. This would appear to be a very rare condition, though, as often happens with rare affections, four such cases have been met with in the last two years; in each the diagnosis has been confirmed at operation. It would appear to be advisable to keep these cases in mind, particularly when recovery is delayed after reduction of a dislocation of the elbow.

## A DIABETIC DIET: THE LINE RATION SCHEME.

BY

R. D. LAWRENCE, M.A., M.D. ABERD.,  
CHEMICAL PATHOLOGIST, KING'S COLLEGE HOSPITAL.

EVERYONE recognizes that the most difficult part of the battle, both for the doctor and the patient, is not the insulin but the quantitative diet necessary in severe cases. A diet should be accurate and simple and yet permit of variety to suit all tastes and purses. If the diet is accurate and simple yet rigid, like Dr. Graham's "ladder" diet, it often defeats its own object by the patient getting tired of the monotony. If the scheme is accurate and still permits of choice and variety, like the scheme of Dr. Harrison and myself,<sup>1</sup> where the prescription of so many grams of carbohydrate, protein, and fat has to be translated into weights of food by the patient himself or his doctor, a few days' training and explanation is required, unless the patient is intelligent.

The following line ration scheme meets the requirements both of the busy doctor and the patient. The doctor has only to divide the patient's weight by a factor to be able to prescribe the correct rations for the day, and two minutes suffice for all the necessary instructions to the patient. Thus treatment can be commenced outside an institution, and no preliminary starvation is involved now that insulin can take its place. The scheme is shown in the appended table. Each complete line is called a ration and consists of a standard amount of carbohydrate, protein, and fat. The diet is prescribed as so many lines, or rations, a day. To calculate the appropriate number of rations the physician has only to divide the body weight in pounds by 16 (16.5 is more exact). Thus if a man weighs 165 lb. he will get 10 rations—that is, ten lines a day. (Unlike the schoolboy, the worse the diabetic the fewer "lines" he ultimately gets.) Each line is divided into two parts: the first half-line containing the carbohydrate and the second half-line the protein and fat. Any first half-line can be combined with any second half-line to make a ration. The number of rations a day is divided as desired between the different meals with regard to when insulin is given and other considerations. Suppose a patient gets three rations for breakfast: he can take  $3\frac{1}{2}$  oz. milk,  $1\frac{1}{3}$  oz. bread, and 4 oz. tomato (three first half-lines containing carbohydrate), and one egg and  $2\frac{1}{5}$  oz. of fat as butter and 2 oz. of bacon (three second half-lines, one of which has been taken twice). Thus the patient can choose his own food. The method is accurate and the lines exact in food value, with the exception of milk, whose content in protein and fat has been neglected for simplicity. The food values used are those of the food tables of Harrison and Lawrence, which are an average from all known authorities. The weight of cooked foods is given unless otherwise stated. The scheme has been planned on the following theoretic considerations.

The common successful practice is adopted of giving diets of low total caloric value composed of low carbohydrate, moderate protein, and high fat content. The proportion of carbohydrate to fat is such as to avoid appreciable acidosis (ketosis), the proportion of fatty acids to glucose being as 1.5 is to 1, as in Wooddyatt's formula.<sup>2</sup> I aim at giving 1 gram of protein per kilogram of body weight (about  $1\frac{1}{2}$  gram per lb.). This is more than many of the American school advocate, but giving less makes a miserable allowance from the patient's point of view. Each ration or line contains 5 grams of carbohydrate (the first half-line), 7.5 grams of protein, and 15 grams of fat (the second half-line). If we give 1 gram of protein per kilogram of weight, a man of 75 kg. will get 75 grams of protein a day. Now each ration contains 7.5 grams of protein, so that  $75 \div 7.5 = 10$ ; this is the number of rations for a man of 75 kg. It is the same thing to divide the weight in pounds—165 by 16.5 (7.5 kg. = 16.5 lb.). Now if we make protein the starting point and look upon it as unity (1 gram of protein per kilogram), the proportion of a ration is 0.66 gram of carbohydrate, 1 gram of protein, and 2 grams of fat, which equal 25 calories. Hence it follows that if we are giving 1 gram of protein per kilogram and the carbohydrate and fat are in the 25 calories per kilogram of body weight (11 calories per lb.). Thus by 16.5 will always give us the number of rations that provide a diet of 25 calories per kilogram of body weight with the carbohydrate, protein, and fat in proper proportion.

The diet of 25 calories per kilogram is low, but makes a good starting point in the treatment. If the patient becomes sugar-free on it the diet can be raised later. If he does not become sugar-free with nearly normal blood sugars at the end of a week, insulin must be given. If the patient is losing weight and energy higher diets can be prescribed by dividing the body weight by other factors. The number of rations to provide a diet of 30, 35, or 40 calories can be calculated by dividing the body weight in pounds by 13.5, 11.8, or 10.3 respectively, the resulting diet still having the proper proportion of carbohydrate and fat to avoid acidosis, but the protein becoming more than 1 gram per kilogram. If this is undesirable, the extra calories can be added to the 25 calorie diet by giving extra carbohydrate and fat in the proportion of one first half-line to  $1\frac{1}{2}$  or 1 oz. of fat—depending on whether the patient tolerates fat well or not. But a few patients may find this confusing, and the harmful effect of slightly increased protein is not clearly proved. Each line ration contains 190 calories, so this another method of calculating the number of rations a day is to divide the total calories desired by 190—1,900 calories being contained in ten rations.

## THE "LINE RATION" DIET SCHEME.

Any first half-line added to any second half-line = one ration.

First Half-lines.	Second Half-lines.
Milk ... .. $3\frac{1}{2}$ oz.	One egg and fat $2\frac{1}{5}$ oz.
Bread ... .. $1\frac{1}{3}$ oz.	Bacon 1 oz.
*Oatmeal (raw) or biscuit ... $1\frac{1}{2}$ oz.	Ham 1 oz. and fat $1\frac{1}{4}$ oz.
Cabbage or greens ... .. 5 oz.	Kipper 1 oz. and fat $1\frac{1}{2}$ oz.
*Tomato (raw or cooked) ... 4 oz.	Herring 1 oz. and fat $1\frac{1}{2}$ oz.
*Potato ... .. $3\frac{1}{4}$ oz.	Lean meat or mutton 1 oz. and fat $1\frac{1}{2}$ oz.
Cauliflower or French beans 6 oz.	Lean lamb or veal 1 oz. and fat $1\frac{1}{2}$ oz.
Brussels ... .. 5 oz.	Lean pork 1 oz. and fat $1\frac{1}{2}$ oz.
Spinach or asparagus ... 6 oz.	Chicken 1 oz. and fat $1\frac{1}{2}$ oz.
Turnip or carrot ... .. 4 oz.	Tongue (tinned) 1 oz. and fat $1\frac{1}{4}$ oz.
Onions, leeks, or marrow ... $2\frac{1}{2}$ oz.	Liver 1 oz. and fat $1\frac{1}{2}$ oz.
Beetroot ... .. 6 oz.	Kidney or tripe $1\frac{1}{2}$ oz. and fat $1\frac{1}{2}$ oz.
Lettuce (raw) ... .. 6 oz.	Rabbit $2\frac{1}{3}$ oz. and fat $1\frac{1}{2}$ oz.
Cucumber (raw) ... .. 5 oz.	Cheese $3\frac{1}{4}$ oz. and fat $1\frac{1}{2}$ oz.
Celery (raw) ... .. 5 oz.	White fish $1\frac{1}{2}$ oz. and fat $1\frac{1}{2}$ oz.
*Apple or pear (raw) ... .. $1\frac{1}{2}$ oz.	Sardines 1 oz. and fat $1\frac{1}{4}$ oz.
Orange or strawberries ... 2 oz.	Salmon 1 oz. and fat $2\frac{1}{5}$ oz.
Rhubarb (stewed) ... .. 6 oz.	Crab or lobster $1\frac{1}{2}$ oz. and fat $3\frac{1}{5}$ oz.
Apples or pears (stewed) ... $2\frac{1}{2}$ oz.	Pheasant, grouse, or partridge $3\frac{1}{4}$ oz. and fat $1\frac{1}{2}$ oz.

Fats are meat fats, suet, dripping, butter, margarine, olive oil; thick cream (twice the amount).

\* These articles to be taken only if specially allowed by the physician.

## Doctor's Prescription.

## Rations per day—

Breakfast: .....  
 Dinner: .....  
 Tea: .....  
 Supper: .....  
 Date: .....

The scheme is elastic and permits of easy modification to meet all requirements. In acidosis all or some of the fats can be omitted for a time. If the carbohydrate tolerance is high or improves, extra carbohydrate can be added as extra first half-lines. It may eventually be found that a quantitative diet has become unnecessary and qualitative restrictions alone will control the disease.

I find the scheme works admirably. From the doctor's point of view it eliminates the lengthy planning of diets; the patient has only to be weighed to calculate his initial diet and subsequent adjustments are easy. Patients themselves can grasp the scheme in two minutes, and the only tax on them is the accurate weighing, to which they gladly submit when they feel the benefit of it. Letter scales modified, and costing four to five shillings, meet the purpose in cases of forced economy; otherwise some type of confectioner's scale is preferable. I use this scheme particularly for out-patients and for those who are not very intelligent.\* Really intelligent patients seem to prefer the scheme of Dr. Harrison and myself, taking a pride in the accuracy and variety of their diets.

## SPONTANEOUS RUPTURE OF THE HEART.

BY

JAMES H. SKEEN, AND D. RUTHERFORD DOW,  
 M.B., M.D.

(From the Anatomy Department, University of St. Andrews.)

We have read with much interest the reports of five cases of spontaneous rupture of the heart recorded in the *BRITISH MEDICAL JOURNAL* for August 30th (p. 373), September 13th (p. 465), and October 11th, 1924 (p. 669). The following is an account of the clinical history and *post-mortem* examination of a heart which had ruptured in a patient under the care of Dr. Skeen, Fife and Kinross District Asylum.

## CLINICAL HISTORY.

The patient, who was the subject of old-standing dementia, died in November, 1922, at the age of 65. During February, 1917, she had cardiac attacks, and again in May, 1921. She was slow in her movements, rather decrepit, and frail-looking. She did not perform any work, but wandered about aimlessly, at a gentle pace. There was never any dyspnoea. The extremities, nose, chin, and ears were occasionally cyanosed. Prior to her death she was walking quietly on a level piece of ground, neither evincing nor experiencing excitement. She was observed to drop down, and died a few moments later.

\* This scheme, amplified and with explanation for doctors and instructions for patients, can be obtained in a convenient card form from Messrs. Lewis and Co.

## POST-MORTEM EXAMINATION.

The heart was small, measuring 3 in. vertically and 4 in. transversely. There was a moderate amount of epicardial fat present.

## Condition of Arteries.

**Aorta.**—The ascending part was soft, pliable, and comparatively free of atheromatous patches, except at its lower part, where one or two were present. The cusps of the aortic valve, especially the right and posterior, were stiffened at their bases with patches of calcification.

**Right Coronary Artery.**—The orifice of this artery, while reduced in size, was not so small as the orifice of the left coronary. On cutting the vessel transversely a quarter of an inch from its origin, its lumen was found to be reduced to a mere slit by the presence in its wall of annular atheromatous thickening. The main stem of the right coronary artery was tortuous and presented patches of calcification along its whole course. Its two branches were also markedly atheromatous. It did not give off a right marginal branch, but divided into (a) an inferior interventricular branch, (b) a terminal branch which passed down

A drawing of the posterior surface of the heart. Before the heart was dissected the perforation appeared as a slit. It became enlarged as the result of manipulation. The right coronary artery and its two main branches are seen. They supply a larger area than usual on the posterior surface of the heart. The posterior branch of the left coronary artery is seen in the drawing.

its termination it was found that its lumen would scarcely admit a pin. The other branch was similarly reduced in calibre.

**Left Coronary Artery.**—At its origin from the sinus of Valsalva its lumen was exceedingly small, but immediately distal to its origin the lumen became perfectly patulous, 6 mm. in diameter. Distally there were patches of atheroma involving rather more than half the circumference of the vessel wall, but the lumen was not greatly reduced. Its anterior branch had numerous patches of atheroma, with the result that at many points its lumen was almost obliterated. Its posterior branch, somewhat smaller than usual, pursued a normal course, but it was also markedly atheromatous, and its lumen extremely narrowed.

**Auricular Part of the Heart.**—Both auricles were normal in appearance. The muscle coats were rather pale, and the walls exceedingly thin.

**Ventricular Part of the Heart.**—The tricuspid valve was normal. The bases of the cusps of the mitral valve were slightly calcified. There was no narrowing of the tricuspid or mitral orifices.

**Left Ventricle.**—For the greater part the muscle wall was thinner than usual. It was six-eighths of an inch at its thickest part and was five-eighths of an inch in the region of the site of the perforation. On the posterior wall about 1½ in. from its apex, and between the two branches of the right coronary artery (see drawing), there was a perforation 1 cm. in length. It passed through the entire thickness of the wall of the ventricle. On examining the interior of the chamber after reflection of the posterior cusp of the mitral valve, it was found that the heart muscle around the region of the perforation was somewhat necrotic in appearance, and the fibres of the heart in this area had ceased to manifest their normal colour and appearance. On microscopic examination of a piece of tissue taken from the posterior wall of the left ventricle adjacent to the site of the rupture the following appearances were found: The muscle fibres were not closely packed together; they had lost their striation and some had no nuclei. Fibrous tissue cells were abundant with large nuclei; they appeared to replace the muscle cells to a large extent.

## REMARKS.

The salient features observed *post mortem* were:

1. Narrowing of the lumen of the right coronary artery, causing almost complete obstruction of the circulation through that channel.
2. Secondary fibrotic and degenerative changes in the cardiac muscle in part of the region supplied by the right coronary artery.

3. The rupture was situated in this region.

4. Degenerative changes were more prone to occur in the specimen described, as the area affected was entirely dependent for its blood supply on the right coronary artery.

It would be of interest to know if the coronary vessels were affected with arterio-sclerosis in the five cases recently reported. In four of them reference was made to degenerative changes in the aorta. Were the orifices of the coronary vessels narrowed in these cases? In some instances they may be quite patulous, while the lumen of the main stems is narrowed as the vessels run in the substance of the heart muscle. In one of the cases reported the aorta showed no sign of disease. It did not follow that the coronary vessels were in a similar condition. The weight of the heart in these cases was worthy of note. In each of the five reported it was found "enlarged." In the case which we have described it was smaller and under average in weight.

Various suggestions have been advanced to account for spontaneous rupture of the heart. It is, without doubt, the result of a diminished blood supply with consequent secondary degenerative changes in the heart muscle, caused by arterio-sclerosis in one or both of the coronary arteries.

## A SIMPLE METHOD OF BLOOD TRANSFUSION IN INFANCY.

BY

GEORGE H. ALABASTER, M.D., F.R.C.S.Ed.,  
QUEENSTOWN, SOUTH AFRICA.

The value of blood transfusion in severe degrees of shock is now generally admitted. I recently had occasion to apply it in a male infant 4 months old, in an extremely collapsed state, when lesser methods of treatment had failed.

After three weeks' enteritis, with associated prelitis due to *B. coli*, the child lay with drooping eyelids, half-closed sunken eyes, waxen face, depressed fontanelle, utterly listless, and apparently moribund. Half a pint of subcutaneous saline given earlier in the day had failed to produce any improvement. Death within the hour was expected by all in attendance. It was decided to attempt blood transfusion, and the method employed seems worth recording in detail, as it proved effective, and gives promise of help in certain wellnigh hopeless cases. The operation was carried out in an operating theatre, but could be performed with little more difficulty in a private house.

A bowl of normal saline, so that the syringe and needle might be washed if necessary, a solution of sodium citrate (6 grains to 1 c.cm. distilled water), and a solution of 1 per cent. novocain with adrenaline, were prepared. Two 10 c.cm. syringes (one as a reserve) with two fine needles, sterilized by boiling, were available. The needles were of medium length, not so fine as hypodermic needles, but finer than the usual exploring needle.

The mother sat with her arm resting on a table in convenient proximity to the child. Venous congestion was produced in the mother's arm with a turn of the handage applied to the upper arm in the usual manner. She was warned to ignore any loss of blood as quite insignificant and unimportant to herself. Her median basilic vein was then exposed under local anaesthesia with 1 per cent. novocain. A ligature was passed beneath the vein, but left untied and gripped with a Spencer Wells forceps for lifting and steadying.

Under novocain anaesthesia an incision was made across the upper part of the child's thigh, about an inch below and parallel to Poupert's ligament. The subsequent steps of the operation are made easier if this incision is long rather than short. The subcutaneous fat was divided, and the vein which lies in the deeper part of the fascia, well to the inner side of the femoral artery, was found. It is important not to prick the vein, and the deeper part of the incision in the fascia was made in the direction of the long axis of the vein, after retraction of the margin of the wound. An aneurysm needle was then passed under the vein, and moved up and down, thus clearing 1 to 1½ inches; the handle of the aneurysm needle falling at the peripheral end of the wound cocked the vein up, putting it on the stretch and steadying it.

Into the syringe and needle 1½ c.cm. of the citrate solution was introduced, and it was then filled with blood from the mother's vein. No attempt was made to stop the bleeding from the mother's vein at the moment, but the syringe was quickly shaken to mix the blood and citrate solutions, and such air bubbles as were present were expelled. The child's vein was now lifted and stretched with the aneurysm needle in position and the needle of the syringe introduced into the vein with its point lying superficially and its bevelled surface deeper; in this manner the point is more easily seen and controlled and less easily driven through the vein wall. With the needle pushed well along the vein the 10 c.cm. of blood were easily and rapidly introduced and the vein tied to prevent any possible haemorrhage; the wound was closed and dressed with gauze and collodion to prevent any unnecessary exposure of the child. There was no shock to the child, who scarcely moved throughout the operation.

The effect was remarkable. I was called away, but returned in three hours to find the child's appearance wonderfully improved. A feed had been taken, and the depression of the fontanelle, which had been very marked, had vanished, and the patient's appearance was no longer that of a dying child.

A second transfusion was performed a few hours later in the hope of intensifying this evidently beneficial effect; 25 c.cm. of citrated blood were easily introduced, using the same syringe and needle all the time, and necessitating three introductions of the needle into the mother's vein and three into the child's vein.

Unfortunately twenty-four hours later the child went into convulsions and died, but I do not associate this with the transfusion in any way, for there were many pus cells in the urine, and there was probably a general blood infection. There was no difficulty in passing the needle into the same wound in each vein each time, and there was not the slightest reflux of blood alongside the needle from the baby's vein; nor, when the needle was removed, was there any escape of blood so long as the peripheral end of the vein was kept raised by the aneurysm needle. Giving antimony intravenously in a stout subject with small veins when dissection was necessary I have found such reflux alongside the needle troublesome, but blood is a more viscid fluid.

Assuming the total blood weight to be one-thirteenth the body weight, it seemed inadvisable to introduce more than 25 c.cm. of blood, and this could easily have been done had it been desirable.

Certain points of detail perhaps call for comment. The child should be kept warm, and as far as possible covered up during the proceeding, about which there need be no great hurry.

The upper end of the saphenous vein was selected because it was one of the largest superficial veins, and was in immediate continuity with the much larger femoral vein, so that the blood would be easily and quickly removed, preventing any tendency to reflux; also there was not the same danger of air embolism which the larger neck veins might offer. It might be urged that the exposure of the mother's vein by incision is unnecessary, but it prevents any possible bungling in the withdrawal of the blood, and the only real need for speed is during the process of transfer.

The very speedy recovery of the child from its collapsed state makes no doubtful whether the depression in the fontanelle and the collapse of an infant in severe gastro-enteritis is as much due to dehydration as to toxæmia, though it is probably caused partly by both. As a practical point arising out of this reflection, the question may be asked whether salines can ever approach whole blood in value, even in early childhood, for the child is suffering from something more than loss of fluid, something salines cannot influence perhaps.

With insufficient experience to express a definite opinion, I would suggest that blood transfusion might prove of very real service in severe degrees of collapse in infancy, whether from gastro-enteritis or from other cause.

## THE TYPE OF CASE THE BONESETTER GETS.

BY

F. WILSON STUART, M.Ch.,

SURGEON, BIRMINGHAM CRIPPLES' UNION; ASSISTANT SURGEON, ROYAL ORTHOPAEDIC AND SPINAL HOSPITAL, BIRMINGHAM AND SHROPSHIRE ORTHOPAEDIC HOSPITAL, ETC.

DURING the past year it has fallen to my lot to manipulate a considerable number of cases of knee-joint trouble, in some the result of adhesions, in others of displaced semilunar cartilages.

The following two cases are, I think, worthy of record as illustrating, first, the type of case the bonesetter often cures and acquires fame in so doing, and, secondly, that which he cannot hope to cure and which sooner or later must come to the surgeon for operative treatment. The youth of one of the cases is rather exceptional. Cases have actually been operated upon at the thirteenth year,<sup>1</sup> and recently a case of reduction of displaced semilunar cartilage at 4½ years of age has been reported.<sup>2</sup>

### CASE I.

A. B., aged 10 years, seen on March 12th, 1924, said he had fallen from the top of a wall nine weeks previously and hurt his right knee so that it was swollen and could not be straightened. At the end of four weeks he was able to get about on it, but the joint was unstable, and he fell frequently. He was taken to a consulting surgeon, who diagnosed a displaced internal semilunar cartilage and advised that a knee-cap be worn. The knee, however, still continued to give way, and two weeks previous to being

seen by me he fell down some steps and had been unable to straighten the knee since.

**Condition on Examination.**—The knee was normal in appearance and all movements were complete except extension, which was not quite complete, there being a sensation of some resilient structure blocking it. This was so slight that it was difficult to realize that there was really anything wrong with the joint. There was no pain on movement nor tenderness on pressure, and the only reply the boy gave to questions was "It's here," accompanying the remark by rubbing the inner side of the joint with his hand. He was then asked to walk, and the disability at once became apparent—he could not get the heel to the ground by quite two and a half inches, and limped across the floor on his toes. The quadriceps was very weak and flabby.

**Treatment.**—The displaced semilunar cartilage was reduced by full flexion, internal rotation, and extension. The boy was able to walk across the room immediately. A back splint was then applied and massage and electrical stimulation of the quadriceps carried out thrice weekly. No movements of any kind were permitted for a fortnight in order that healing of the torn parts should take place undisturbed. At the end of a fortnight the back splint was discarded and a bandage substituted. In spite of some tenderness over the inner side of the knee movements were begun. At the end of another fortnight the bandage was left off and treatment continued in the gymnasium for another week, when the boy was discharged.

During treatment in the gymnasium the joint was subjected to all sorts of twisting movements, but it stood the test, and the subsequent history proves the completeness of the cure—there has been no further trouble. This is rather remarkable in view of the length of time which elapsed between the first accident and the manipulation.

### CASE II.

Miss C., having hurt her right knee two days previously, was brought to me on the evening of Easter Monday. She gave a history of its having been "out" many times before, but she had always been able to get it "back" herself; on this occasion she could not.

**Condition on Examination.**—The knee was flexed, much swollen, and very tender; all attempts to move it were strongly resisted by powerfully contracted muscles and produced so much pain that they had to be abandoned.

**Treatment.**—Next morning she was given an anaesthetic and the knee fully straightened quite easily by manipulation. Extension was accompanied by a sound as of something tearing inside the joint. After treatment as in Case I was carried out, but, owing to the history of frequent displacement, operation was advised. Before this was done the cartilage again became displaced and again was reduced by manipulation—this time without an anaesthetic.

After this there was always a feeling of something moving inside the joint, and at operation the cartilage was found to be detached along the periphery in its posterior two-thirds—a condition to which I give the name "sickle-shape." In this position the detached portion of the cartilage is bent diagonally across the front of the internal condyle of the femur, so that any reduction which could take place by manipulation would result in tearing away more of it from the coronary ligament. Removal of the whole cartilage resulted in a complete cure.

## THROMBO-ANGITIS OBLITERANS.

BY

CHARLES DICKSON, M.C., M.D., F.R.C.P.I.,

DUBLIN.

THE interesting paper by Professors Telford and Stopford of Manchester on thrombo-angitis obliterans, published in the *BRITISH MEDICAL JOURNAL* of December 6th, 1924, provides a reasonable diagnosis in a somewhat obscure case recently under my care. The parallel as regards signs and symptoms is close, but as there is a striking contrast in the matter of age and course to date it is thought worthy of record.

The patient is about to complete his 86th year, and, although a lifelong fisherman, I am sceptical of any ground for connecting this fact with the present condition, as is done in one recorded case. The family history and personal history are both exceptionally good. Some months previous to the first attack there had been acute suppurative of a corn situated over the metatarsophalangeal joint of the great toe of the right foot. In the beginning of March, 1924, after a slight attack of bronchial catarrh and flatulence, sudden pain was felt in the upper third of the right calf. When I examined the leg several hours later the foot was swollen and oedematous to the ankle, especially over the dorsum of the foot, and of a reddish colour. The limb was stone cold as high as the junction of the middle and lower thirds of the leg. Walking was impossible on account of the pain, which was described as "cramp."

like." Relief was obtained when the limb was raised, but when in bed at night there was a subjective sensation of heat in the stone-cold foot; this was relieved to some extent by resting the foot outside the bedclothes. No arterial pulsation could be detected below the level of the popliteal space, and a provisional diagnosis was made of arterial obstruction somewhere in the region of the popliteal bifurcation. There was an old-standing ingrowing toenail on the great toe of this foot, and the ingrowing portion was removed without injury to underlying tissues. Massage was avoided, and treatment consisted of rest with the limb raised, and daily application of methylated spirit, ether, and Huxley's powder, to minimize the risk of sepsis. Little else was required, as the patient was unusually healthy for his age. The heart, which was irregular, was supported from time to time, but perhaps unnecessarily, and at one period potassium iodide was tried, until the excretion of iodine in the saliva caused some faucial irritation and it was discontinued.

At the end of about three weeks the appearance of the foot suggested the formation of a line of demarcation in the neighbourhood of the ankle-joint. Gradually, however, circulation in the skin capillaries became brisker, the oedematous swelling diminished, and, after two months, walking became possible, though attended for some time by pain, due possibly to relative ischaemia in the muscle of the calf on the affected side. This condition of claudication gradually disappeared entirely, but for about four and a half months from the initial attack some pain persisted in the region of the instep on walking. A small "blood blister" appeared at the site of the ingrowing toenail. It, however, sloughed off, leaving healthy skin behind.

The patient has a high degree of natural immunity to ordinary sepsis, and this no doubt contributed to some extent to the favourable result. At the end of five months the foot was perfectly normal again, the last portion to lose its oedema and resume its normal appearance being the outer half of the dorsum of the foot.

Five and a half months after the onset of the first attack a similar sudden and intense pain was felt in the calf of the other (left) leg. The same sequence of events followed, differing only in degree, the second attack being in every way less severe and no superficial slough appearing, although an ingrowing toenail on this foot also was similarly dealt with.

At the moment of writing (four and a half months later) this foot also is practically normal in appearance. No pain is now felt in either limb when at rest or when walking short distances up to 200 or 300 yards. When this distance is exceeded a condition of claudication supervenes, affecting the left leg only and necessitating rest for a few moments. With judicious resting (by means of a camp stool) daily walks of a mile or more can be enjoyed without fatigue.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### CUTANEOUS GONOCOCCAL INFECTION.

A medical man consulted me recently on account of a curious dermatitis of the elbow. A slight abrasion of the skin over the olecranon was caused by a fall while playing football, and a week later the lesion became acutely inflamed and very painful. On examination the abrasion was found to have become a shallow ulcer,  $2\frac{1}{2}$  cm. in length by about 1 cm. in width. Its base was formed by a lemon-coloured slough, and the edge was surrounded by a hyperaemic band of skin some 2 mm. in width. Encircling the ulcer, at a distance of about 3 cm., were a number of bullae; the smallest was 1 cm. in diameter and the largest  $2\frac{1}{2}$  cm. long by 1 cm. broad. The axillary glands were enlarged and tender. Serous fluid was obtained by the aspiration of one of the bullae, and films stained by Gram's method showed a few pus cells with intracellular Gram-negative diplococci morphologically resembling gonococci. A few Gram-positive cocci were also present. From cultures on blood agar *Staphylococcus aureus* and a Gram-negative diplococcus were obtained. Colonies of the latter on serum agar developed the scalloped edge characteristic of gonococcal colonies after four days' incubation. There was no history of gonorrhoea, so that a metastatic explanation of the infection was untenable, but, in view of the rarity of a primary gonococcal cutaneous infection, fermentation tests were undertaken to establish the identity of the organism. Glucose was fermented, but maltose and saccharose were not. No growth was obtained on broth

agar, and from these criteria it was concluded that the organism was in fact the gonococcus.

Inquiries as to the probable source of infection elicited the fact that, three days before the elbow became painful, the patient had operated on a female for elephantiasis. At the time of operation there was a vaginal discharge, but subsequent examination failed to detect any gonococci.

The course of the cutaneous lesion was uneventful. Hot fomentations were employed for twenty-four hours and then protargol was applied. Three weeks later healing had occurred.

#### CASE OF PROTEIN ANAPHYLAXIS.

My son, aged 8 years, had occasion to take delivery of a hare (dead) at the railway station distant about five minutes from my house. He wrapped the hare round his neck, and in this manner carried it home. A few minutes after his arrival he was seized with intense itching in his eyes, which at once became deeply congested. This was followed by a copious watery secretion from the nares. A few minutes afterwards a livid erythematous rash appeared on the neck; it spread rapidly on to the face, and was followed by marked oedema of the eyelids. At night a persistent hacking cough developed, which continued during the night. At 2 a.m. on the two following nights he was seized with a typical attack of asthma, which compelled him to sit up in bed. The oedema of the eyelids lasted for about three days. Bronchial râles were heard over both lungs.

I ordered the nares and pharynx to be sprayed with an alkaline douche, and for some days small groups of hairs appeared in the return water. Sensitization tests were applied a week afterwards, the result being marked positive reaction to the epidermal groups (Nos. 25 and 26).

The following points are interesting: (1) The facility in detecting the protein causing the symptoms; (2) the rapidity of onset and the course of the symptoms; (3) the marked reaction to the tests applied.

I may add that the boy on many occasions had been in contact with dogs, cats, and horses without any ill effects.

AYR.

FERGUS MCKENNA, M.B., C.M.

#### RECURRENT CHICKEN-POX.

WHILE it is clear from the experience of many practitioners that one attack of chicken-pox does not necessarily confer immunity to the disease, and while, according to Osler and McCræ,<sup>1</sup> there are instances on record of three attacks in one person, the following particulars of a family under my care, the members of which appear to be unusually susceptible to the disease, seem of sufficient interest to report.

Of the three children in the family Mary was born in 1916, John in 1919, and Lucy in 1921. Their first attack occurred during a holiday in Cornwall in September, 1921. The eldest child was slightly affected, and the boy rather badly. The third child, then a baby of 7 months, had one or two "spots" (a doubtful case). There was a small outbreak of varicella at the time in the neighbourhood, and Dr. F. C. Matthew of St. Ives, under whose care the children were, has written to say he remembers the circumstances quite well, and had no doubt as to the diagnosis. The remains of the eruption were visible on the patients on their return to Oxford. In July, 1922, Mary had what I regarded as a mild attack of chicken-pox, for which she was isolated. In October, 1924, following the occurrence of a case at her school, she had a rather severe attack. Thirteen days later John fell ill, and Lucy two days after him. All three were typical cases in respect of the onset, character, distribution, and duration of the eruption.

In this family, therefore, two of the children have each had two definite attacks, the eldest almost certainly a third, while the youngest member has had one clear attack and one doubtful. The subsequent history of these children will be noted with interest.

## Reports of Societies.

### LEPTOSPIRAL JAUNDICE IN DOGS.

At a meeting of the Section of Comparative Medicine of the Royal Society of Medicine held on January 28th, with Mr. FREDERICK HOBDAY, the President, in the chair, Dr. O'KELL and Messrs. DALLING and PUGH read papers on the subject of leptospiral jaundice in dogs. The research on which the papers were based was the joint work of the three authors, but each contributed a paper dealing with somewhat different aspects of the question.

Dr. C. C. O'KELL, in giving his reasons for considering that canine enzootic jaundice was a leptospiral disease, said that of the ten cases investigated he and his collaborators had been able to isolate the organism in three dogs. He believed that they had satisfied the postulates of etiology usually required in such cases. The characteristic appearance of the organism and the peculiar *post-mortem* picture made it easy to decide that they were dealing with a leptospiral infection. They were unable, however, invariably to demonstrate the causal organism. Indeed, in only one case could they definitely see living leptospirae in ground-up preparations of various organs. In this case the guinea-pigs inoculated with the material showed no symptoms, but cultures produced many organisms which, on inoculation and subinoculations into experimental animals, were observed in ground-up tissues. With this strain they were able to show that rat serum and recovered-dog serum protected guinea-pigs against injections of the virus, while normal horse and dog serums did not. In unprotected animals the strain proved to be fatal. Krumben and Fricling, in 1916, reported that two men, living in the same room as a dog suffering from jaundice, developed what appeared to be typical Weil's disease, although these authors did not appear to be able to confirm the nature of the infection. Later authors had reported the disease as occurring in the dog under natural conditions.

Mr. L. P. PUGH said that the disease might be divided clinically into main types, with, however, every gradation between them. (1) The *hyperacute haemorrhagic type* was characterized by its sudden onset and high initial temperature (104°-106° F.), which, however, immediately before death always fell to 97°-98° F. (The normal rectal temperature of the dog is about 101°-102° F.) There was intense depression and sometimes symptoms of meningitis. Epistaxis was common and bronchial râles very evident. Vomiting, often blood-stained, occurred in all cases, and thirst was pronounced. The urine was passed in small amounts and had a high albumin content. Other symptoms were variable, but, as a rule, icterus was absent. The course was rapid, and dogs died in a few hours or days. (2) The *icteric type* had a variable onset. In the rapidly fatal type with jaundice it was acute; in the milder cases it was very insidious. The initial temperature was about 102°-103° F., which became subnormal before death. The marked depression of the first type was absent in the early stages, but developed later. Vomiting was constant and constipation usually marked. The urine was bile-stained and contained much albumin. Emaciation was frequent. Acute cases might die within two days; milder cases might survive for a week or more. Associated with outbreaks, cases occurred in which the dogs showed a slight fever and transient gastro-intestinal disturbances; these, Mr. Pugh considered, might ultimately prove to be mild cases of the disease. In the course of the work blood was examined for the presence of intracorpuseular parasites, but none were found. Moreover, trypan-blue, which proved so useful in piroplasmiasis, was useless in treatment. It was too early yet to state that the administration of antileptospiral serum would effect cures, but, although results were promising, he preserved an open mind. He recommended the use of liquid paraffin and enemata of normal saline in cases in which treatment was attempted. A liquid alkaline diet was of advantage.

Mr. T. DALLING, in comparing natural and artificial infections, said that of the ten naturally infected cases examined three showed the hyperacute type of symptoms, while the others were icteric. In the experimental

animals none were icteric. The resemblance between the series was striking, with many features in common. In both the *post-mortem* picture was identical. All degrees of jaundice might be observed. All the abdominal vessels were congested, while petechiae might be found in any part of the intestine. Intussusceptions were frequent. The liver was enlarged and congested or pale and icteric. The lungs showed bright-red punctate haemorrhages of varying size and situation. Haemorrhages might be found in practically all organs except the central nervous system. Rats might be regarded as healthy carriers of the disease, and were probably the main vectors of the virus. In the only two infected kennels investigated virulent leptospirae had been found in the rats. Mr. Dalling thought that natural infection was by means of contaminated food and bedding. The discovery of leptospirae in the kidney of one dog suggested that infected animals might themselves transmit the disease by soiling bedding with their urine. Guinea-pigs could be protected against a lethal dose of leptospirae of canine origin by an immune serum. Dogs exposed to natural infections could be similarly protected with 5 to 10 c.cm. of the serum. He considered that the disease might be—provisionally at least—differentiated from distemper by a number of points. In distemper the temperature was persistently high, while in this disease the early high temperature dropped to normal or subnormal, followed sometimes by a sudden short rise and a second fall. Haemorrhagic herpes and blood-stained vomit were very characteristic of leptospiral disease. It was thus easily distinguished from typical distemper, but in border-line cases diagnosis on clinical grounds was often impossible.

The papers were illustrated by charts and numerous pathological preparations. In the ensuing discussion Dr. A. STOKES stated that in the war-time investigation of the human disease it was found that the virulence of the organism in rats in various areas seemed to vary, and he suggested that possibly some crisis arose in the carrier which enabled it to become infective. The difficulty of isolating the organism was not confined to dogs; he had found that it could most frequently be recovered about the fourth day from the kidneys. In man, many cases, though infective, did not show symptoms of jaundice. Dr. A. BALFOUR pointed out that the results had a significance not confined to this country, but that abroad the work might have possible bearings on various human diseases. He drew attention to the possibility of the disease being carried by water, and instanced one case in which a man seemed to have acquired the infection by falling into the Thames.

### ENCEPHALITIS LETHARGICA.

A MEETING of the Aberdeen Medico-Chirurgical Society was held on January 22nd, the President, Dr. PETER HOWIE, in the chair, when Dr. A. G. ANDERSON read a paper on encephalitis lethargica.

Dr. Anderson's experience of the disease extended to some twenty cases, and as the time was inadequate to deal even with one limited aspect of the disease, such was its varied symptomatology, he thought it better to discuss the various points of interest which had emerged from the study of his own cases. After describing the original appearance of encephalitis lethargica in 1917 and its spread in different countries, and stating that the description of "lethargic" was now inapplicable to many of the recent cases, Dr. Anderson related the details of the first case he had seen, on March 17th, 1920, in a woman of 37, who presented the typical features of fever, ocular disturbance, and lethargy, which lasted for seven or eight days. The most interesting feature was that in a few days the mask-like facies developed, and by the end of May the typically stiff gait, resembling that of paralysis agitans, had appeared. During the next two or three years the residual phenomena noted were the mask-like face, the stiff hesitating movements of the limbs—the arms being held in the characteristic mid-brain attitude—and the "ready tire" of the muscles. In this case, fortunately, the Parkinsonism was not progressive, and during the past year the patient had emigrated and was able to do active work. Dr. Anderson then discussed the development of the mid-brain syndrome, and remarked that this was now regarded as one

of the commonest sequelae of encephalitis lethargica, the time of its appearance being extremely variable.

In the description of further cases of the series, Dr. Anderson dealt fully with the various characteristic symptoms and signs which had appeared, and discussed their features especially as regards period of onset and diagnostic and prognostic import. Such were Parkinsonism, lethargy, muscular and mental passivity; the running gait, akinesia, paradoxical disorders of speech, tremors, emaciation, excito-motor phenomena, pain, myoclonus, chorea, athetosis, spasmodic tics and automatic movements; facial paralysis, and signs simulating meningitis. One patient had had two pregnancies after the onset of the encephalitis, a healthy child being born; the case illustrated the facts that encephalitis does not necessarily lead to premature labour, that the child need not be infected, and that pregnancy seems to have a definite effect in aggravating an existing Parkinsonian syndrome. In connexion with the choreic type, Dr. Anderson described fully two cases: one a boy of 14 who had attacks nightly, lasting about four hours, when he went through a series of "antics"—coughing, snorting, jumping in and out of bed, and so on—till he fell asleep exhausted. The other case, also, a boy of 14, had similar restless attacks with very marked insomnia, the wakefulness persisting till 4 or 5 a.m.; one period of insomnia lasted for forty-eight hours. This boy also had attacks of marked respiratory disturbance. The mental and moral changes in the disease were next discussed, and their problems indicated.

In conclusion, Dr. Anderson dealt with the theories of the infective nature of the disease, referring to cases which might lend clinical support to the idea. He also briefly referred to the necessity for a complete examination of the cerebro-spinal fluid in all cases, not so much for possible positive findings as for information enabling other diseases to be excluded. He stated that there was no really characteristic picture of the cerebro-spinal fluid in encephalitis lethargica except that it differed from most other diseases in that the sugar content was invariably high. He pointed out also that in this disease the virus remained in the nervous system for long periods of time, waking into activity at intervals, and affecting different parts of the brain at different times; so that the original conception of a disease with an acute stage passing off and then followed by certain residual phenomena was no longer tenable. No form of treatment so far had been found to have the slightest effect, but in his opinion any form of effective treatment which might be discovered would probably be in the nature of an antiserum rather than drugs.

At a meeting of the Chelsea Clinical Society on January 20th, Dr. GORDON LANE, the President, in the chair, Dr. A. FEILING showed two boys with marked signs of pseudo-hypertrophic muscular paralysis. Mr. L. ADEL showed: a boy with osteomata on the phalanx of one of the fingers and on the metacarpal of the thumb; a case of osteomyelitis and one of osteogenesis imperfecta associated with multiple fractures; a case illustrating the advantage of avoiding the lacrymal apparatus in resection of the upper jaw for malignant disease; and a man with osteo-arthritis of the sterno-clavicular joints and one hip. Mr. A. R. THOMPSON showed a girl with bilateral renal calculi, who presented some evidence of stunted growth, which might have been associated with the renal trouble; also two men who had had the penis amputated for epithelioma—in one case four years ago and in the other case five years ago; one of the patients had become the father of a child since the operation. Mr. IVOR BACK showed a case of dermoid of the floor of the mouth, and also a specimen of sarcoma of the fibula. The President showed a case of blackening and hypertrophy of the nails of the hands, and to a less extent of the feet, which he suggested might be due to a psychic influence, as the patient gave an account of a most gruesome occurrence during the war. Dr. ERNEST YOUNG demonstrated his duodenal tube, which had been of much service in cases of gastric trouble, and could also be used for medicaments and food, distributed to the duodenum without the intervention of the stomach. Dr. J. D. ROLLESTON described a case of erythema infectiosum, which he illustrated with photographs. He suggested the name of "fifth disease" for it, thus carrying on the name of fourth disease, of which he said there were undoubted examples. He suggested that there might be epidemic conditions of the disease, but so far it had not occurred in epidemic form in England.

## Rebifus.

### THE TREATMENT OF FRACTURES.

WHEN a wild animal suffers fracture of a bone it either dies or recovers without any treatment. In the latter case the provisional or ensheathing callus takes the place of splint and bandage. Like Rousseau, Mr. J. W. DOWDEN of Edinburgh would have us go back to Nature, and in his *Principle of Early Active Movement in Treating Fractures of the Upper Extremity* he advocates abandonment of splints even in compound fractures, and the encouragement of movement instead of its prevention. This is an even more revolutionary proposal than was that of Lucas-Championnière, but we are bound to say that in the excellent illustrations of this book Mr. Dowden brings forward strong arguments to justify the adoption of his method in certain cases.

He tells us that he thinks it is possible to put into practice the same principle of treatment in the case of fractures of the lower extremity, although the weight-bearing function of the lower limbs makes a very great difference. It would be interesting to see a collection of photographs and radiographs of fractures of the thigh and leg treated by similar methods, and we hope that Mr. Dowden will ere long be able to produce a companion to the book now under notice. No doubt in order to prevent shortening some means of extension would have to be adopted, which would make the practice of active movement difficult.

It is probably very true that in former days far too much stress was laid on restoration of anatomical form and prolonged fixation. Lucas-Championnière showed us that, especially in the case of fractures near joints, better results could be got by early removal of splints and massage and passive movements; and although in some cases in young persons a too exuberant callus formation resulted, yet the method undoubtedly constituted a great advance in the treatment of fractures, and it is now generally practised by many surgeons.

Mr. Dowden has evidently worked on the sound orthopaedic principle that function is all-important. In the case of the humerus, for instance, he does not trouble himself about end-to-end contact and sometimes disregards overlapping, yet the results, especially in young people, are surprisingly good, as is shown in the radiographs of cases of fracture of the neck of the humerus, on which an almost normal head and neck has been reconstructed in the course of time. A considerable shortening of the period of disability is claimed for this method, but we venture to think that in this respect as good results can be obtained by the method of Lucas-Championnière when judiciously followed, and we question whether the results of complete rest of a non-infected joint or muscle are quite so disastrous as Mr. Dowden states. Something also must be said for the value of appearances. For instance, fracture of both bones of the forearm, if treated without splints, is bound to leave some deformity behind it, and, although a bent forearm may be functionally efficient, it may be strongly objected to by its owner or his friends on aesthetic grounds. Mr. Dowden is a distinguished surgeon of striking and persuasive personality, and is able to induce timid patients to practise voluntary movements of a broken limb when younger and less authoritative persons would fail, and he doubtless runs far less risk of an action for malpraxis on account of an unsightly though useful limb than would a general practitioner with perhaps no special surgical prestige. Nevertheless, such an original and fearless innovation as this is of great value, and, when cautiously tried and tested by others in a favourable position so to do, may lead to great improvement in the routine treatment of fractures.

We strongly recommend the careful study of this book to all those concerned in the care of injuries, and especially to surgeons in industrial districts, to whose patients rapid restoration of efficiency is of such great importance.

<sup>1</sup> *The Principle of Early Active Movement in Treating Fractures of the Upper Extremity*. By J. W. Dowden, M.B., F.R.C.S.E. Edinburgh and London: Oliver and Boyd, 1924. (Demy 4to, pp. ix + 111; numerous plates, 16s. net.)

## PHYSIOLOGICAL AND PATHOLOGICAL CHEMISTRY.

We have much pleasure in welcoming the appearance of a ninth edition of Hoppe-Seyler's handbook of physiological and pathological chemistry.<sup>2</sup> This historic textbook first appeared in 1858 as a small volume of 300 pages, and continued for two generations to be the standard textbook in biochemistry. After the death of the original author two editions were brought out by Dr. H. THIERFELDER; of these the second appeared in 1909. After this date Abderhalden's encyclopaedic textbook of biochemical technique became the standard reference book, but it has now swollen from an encyclopaedia into a library, and so, after an interval of fifteen years, a fresh edition of Hoppe-Seyler's textbook has been prepared. It contains over 1,000 pages, and has been completely rewritten by Dr. Thierfelder and nine contributors.

There are three sections. The first deals with general chemical and physical methods, but it consists of only 35 pages, and therefore only gives a short outline of a few of the most important methods. The second section, of 600 pages, is the most important part of the book. It is devoted to the description of the methods of qualitative and quantitative analysis, and of isolation of the constituents of the animal body. The third part contains details of the chief methods of analysis of animal tissues, fluids, and concretions. The whole work forms an excellent book of reference, containing descriptions of nearly all the standard methods of biochemistry. The subject has, however, been treated from a somewhat conservative standpoint, for very little is said about such modern developments as the special methods of colloidal chemistry. Furthermore, attention is devoted chiefly to substances with a well recognized structure, and only brief mention is made of vitamins; insulin is not mentioned. As a whole it may be said that the volume deals fully with biochemistry from the aspect of organic chemistry, but rather scantily with the physical and physiological aspects of the subject.

Professor MEYERHOF of Kiel has collected five lectures, delivered at Cambridge in 1922, and in a more detailed form at the Rockefeller Institute, New York, in 1923, as a small book entitled *Chemical Dynamics of Life Phenomena*.<sup>3</sup> It appears as one of the Monographs on Experimental Biology, in which series several very useful and stimulating books have already been published. Professor Meyerhof is well known to physiologists for his work on muscle contraction, and it will be sufficient to announce to them that the book has appeared. Its five chapters deal with the physico-chemical mechanism of cell respiration, autoxidations in the cell, chemical relations between respiration and fermentation, the transformation of energy in muscle, and the energetics of cell processes. Readers other than trained physiologists may have difficulty in following the text in some places, but refreshing reward for effort is to be found in the extremely interesting generalizations scattered throughout the book, particularly at the beginning and end of each chapter. There is no statement that the lectures have been translated into English from a foreign language, and certainly this would not be guessed from reading the text. In fact, the book is unusually well written, clear, and without any ambiguity of language, and often eloquent. It contains an extensive bibliography, and is well indexed.

## THE ERYTHROCYTE AND HAEMOLYSINS.

THE latest addition to the English series of Biological Monographs and Manuals edited by Dr. F. A. E. Crew and Dr. D. Ward Cutler is a small book written by Dr. ERIC PONDER, Lecturer in Physiology in the University of Edinburgh, entitled *The Erythrocyte and Haemolysins*.<sup>4</sup>

*Monographs on Experimental Biology. Phenomena.* By Professor Otto Meyerhof. 1923. (Extra post 8vo, pp. 110; 8 figures. 12s. 6d. net.)  
*The Erythrocyte and the Action of Simple Haemolysins.* By Eric Ponder. Biological Monographs and Manuals. Edinburgh and London: Oliver and Boyd. 1924. (Demy 8vo, pp. x + 152; 11 figures. 12s. 6d. net.)

with the morphology, chemistry, and structure of erythrocytes, and the second with the action of simple haemolysins. In the first part of the book there are chapters on the red blood corpuscles of mammals, camels, birds, reptiles, amphibia, fishes, and invertebrates. In the second part the author deals separately with the action of haemolysins on the red cells of mammalia and on nucleated red cells. These two parts lead up to a general theory of the mechanism of haemolysis, which is the substance of the concluding chapter of the book. Herein Dr. Ponder criticizes the opinion of Arrhenius that haemolysis may be described by a formula applicable to mononuclear reactions, and also the views of Chick and Eijkman to the effect that the cells undergo rapid cyclic changes in resistance. In the author's experience these theories do not explain the observed facts. He finds, however, that difficulties may be removed by the assumption that red cells are not all of the same resistance to the action of a haemolytic agent; this assumption is supported by a certain amount of experimental evidence. He writes (p. 179):

"One explanation seems applicable to all the haemolysins considered: that the cells differ in their resistance to the haemolysin, that these different resistances are distributed according to an ideal frequency curve, that the rate of the reaction resulting in the haemolysis of the red cells is of practically constant velocity—this being due to the fact that it is observed over a short time only—and that all variations from the symmetrical form of percentage haemolysis curve are due to accelerations or inhibitions, produced principally by the haemoglobin liberated from the cells."

Haemolytic reactions have been made to serve useful purposes in clinical pathology, as, for instance, in the Wassermann reaction and in the classification of streptococci according to their haemolytic properties. These more complicated examples of haemolysis are not discussed at length in this book, but the careful study of the action of simple haemolysins which the author has made will prove interesting and suggestive of further research to those who have to employ the more complicated haemolytic reactions in their regular work.

## THE LYMPHATIC SYSTEM.

PROFESSOR ACHARD has written a condensed but illuminating account of the lymphatic system which is the more valuable because its author has carried out a large number of researches into the physiology and pathology of what he calls appropriately the "lacunar" system.<sup>5</sup> In a sense the proper understanding of the workings of this system is absolutely fundamental in human physiology for the excellent reason that the lymph is the omnipresent medium bathing every cell, which brings to the cells all their nourishment and which carries from the cells all their waste products. The blood itself is in contact with no tissues except the vascular endothelium, the splenic pulp, and some cells in the red bone marrow.

Professor Achard distinguishes two great classes of liquids in the lacunar system:

1. Those whose function is to act by means of their volume in a mechanical fashion, maintaining pressure in the interior of organs—for example, intra-ocular and intra-aural pressure; or to prevent mechanical injury—for example, the cerebro-spinal fluid and the amniotic. Such fluids Dr. Achard conveniently calls "serosities"; they possess cell nourishment in the form of relatively large amounts of crystalloids.
2. Those whose function is to lubricate surfaces, which they do by their viscosity; they are present in small quantities; they contain relatively large amounts of protein—for example, the "mucosin" or synovin of synovial fluid.

The author is particularly successful when describing the histological and biochemical aspects of inflammation as it affects the areolar tissue and the great serous sacs. The precise causes of those deviations from the normal which constitute oedema and the various forms of dropsy are investigated in an interesting fashion. The therapeutics of these conditions are not omitted; a good deal is said about the sodium, potassium, and calcium ions. Absorption from tissue spaces receives much attention, as well as the rationale of such diuretics as sodium sulphate and urea.

In an appendix are collected together the analyses of a large number of normal and abnormal lymphatic fluids,

<sup>5</sup> *Aperçu de la physiologie et de la pathologie générales du système lacunaire.* Par Ch. Achard. Paris: Masson et Cie. 1924. (Med. 8vo. pp. 225; 29 figures. Fr. 10.)

somic of which, as the author admits, are not of recent date. They are not, however, valueless on that account.

We miss any reference to the work of Halliburton and Dixon on the secretion of cerebro-spinal fluid, and to that of Starling and Henderson on intraocular tension. In fact, English as distinct from American research work is only sparingly quoted. There is no index.

#### KALA-AZAR IN ASSAM.

LIEUT.-COLONEL McCOMBIE YOUNG's book on *Kala-azar in Assam*,<sup>6</sup> giving an account of the preventive operations under his administration, constitutes a remarkable record of the good which can be achieved by rational application of deductive knowledge to questions of public health, even though the problem of the actual mode of conveyance of a disease is still unsolved. The work itself illustrates in several points the fulfilment of the prophetic utterances of Sir Leonard Rogers a quarter of a century ago, referred to by him in a foreword. One example may be cited: "A series of unhealthy years, such as the malarial prevalence in North-east Bengal in 1872-1877 . . . might at any time light up a further epidemic prevalence," wrote Sir Leonard Rogers, and on page 3 of this book it is stated: "It appears that the sequence of events which led to the present recrudescence is . . . a succession of unhealthy seasons" culminating in the years of the influenza pandemic.

The Government of Assam ordered a survey to be made in 1912-13, which showed that certain endemic areas of the disease had persisted in the track of epidemic fires. The author demonstrates how the broad history of kala-azar in each district is traceable from the census returns of the last fifty years, and illustrates this by quoting the figures for several districts, of which Goalpara and Lakhimpur may be mentioned as instances on the one hand of an endemic area in a quiescent period, and on the other of a district so far untainted with kala-azar of the dangerous type. A minus variation in the population during a given decade indicates a prevalence in it of endemic kala-azar during those years. In the succeeding chapter evidence is adduced from both epidemiological and clinical observations to show that the notorious Burdwan fever was kala-azar.

The importance of evacuation of an infected site is demonstrated, and is attributed to the fact that the presence of an infected person is not sufficient alone to start an outbreak, but that some cycle of events conveniently designated "site infection" must be established in and around the house. Hence the beneficial, but not entirely successful, effects of removal of the infected family, for, unless those living in the immediately adjoining houses are removed also, experience shows that cases will arise amongst the latter within a year of the removal of the former. At the same time migration must be prohibited, else scattering of the infected will lead to fresh "site infection," and each such infected site will constitute a focus for further outbreaks. If an acute outbreak arises the best means at present known of preventing spread is early removal combined with treatment of patients. If infection has remained unrecognized, site infection is set up, and unless these patients are removed as well as treated no amount of treatment will prevent a constant crop of cases. Compulsory treatment with tartar emetic administered intravenously has "converted a disease with a 90 per cent. mortality into one with a 90 per cent. rate of cure." The first hospital for kala-azar was built at Nazira in Sibsagar, and the number of cases applying for treatment increased to such an extent that many similar hospitals had to be erected. In 1920 the number of cases treated was 7,188, but it was estimated in November, 1923, that there would be over 37,000 for the year and more than 80,000 in all. The total amount of the drug given was 2 grams spread over a three months' course of bi-weekly injections, but when it was found that patients apparently cured might still harbour the parasite the rule was adopted that "if the temperature becomes normal after two weeks, the treatment is continued

for two months; if the rise of temperature persists for three weeks, treat for three months, and so on."

In the chapter on the distribution of the disease in Assam and in India it is shown that soil *per se* has little influence, but that the conditions of temperature and the degree of humidity which prevail, aided by density of population, are important factors. The succeeding chapter deals with statistics and does not lend itself to summarization. In a final chapter the problem of transmission is considered, though this subject is beyond the original scope of the work. The evidence so far available indicates some insect vector, but until this question is solved preventive measures, though they may be attended by considerable success, cannot be regarded as complete.

The book is well printed and well bound, the photographs and charts are excellently reproduced, and the author is to be congratulated on good work well carried out and interestingly described.

#### GUY PATIN.

THE history of the period immediately preceding and including the reign of Louis XIV, particularly that of his minority and following years, attracts the general reader because letter writers, historians, and novelists have furnished innumerable anecdotes interesting to all those who make no demands for meticulous accuracy. Dr. FRANCIS PACKARD in his *Life and Times of Ambroise Paré* had as the central figure an attractive personality. In his *Guy Patin* he gives a detailed description of the medical world in Paris during the period following that previously dealt with, but he is not so fortunate in his subject, for Guy Patin is neither an attractive personage nor one who helped to advance the medical art of his day; indeed, the converse may be said of Guy Patin, who became one of the most conspicuous physicians in Paris during the minority and subsequent early years of the period of Louis XIV. He was a profuse letter writer, and his letters were preserved because of the anecdotes, criticisms, and satires, abusive and scurrilous, directed against those at the head of the Government, Richelieu and Mazarin in particular, and also against the nobility, Roman Church, and Jesuits. With politics Patin mingled a defence of the Paris Medical Faculty in opposition to their rivals of Montpellier, to the surgeons of Saint-Côme, and to the apothecaries, barbers, and quacks. There have been editors of his letters, each condemning his predecessor for mistakes due to crabbed handwriting in the MSS., and for differences of opinion as to the interpretations to be put upon the antiquated phraseology, and on the allusions and nicknames. Omissions have been excused of anecdotes as untrue and scandalous, of language unlicensed in character or descending to the obscene. Such omissions (bowdlerizing), many consider, tend to decrease the interest which caused the letters to be preserved, and to leave a residue of dreary reiteration over quarrels between the Faculty and the rest of those practising medicine, together with an equally sterile account of Patin's practice and that of his rivals.

Guy Patin (1601-1674), born of well-to-do parents who gave him a learned education, rose rapidly, as a fluent and incisive eloquentist, as well in Latin as in French, through various offices in the Faculty until he succeeded Riolan as professor at the Collège Royal. Meanwhile he obtained a considerable practice, and his wife had money. His primary treatment was blood-letting for all diseases at all stages; in particular he bled young children, also himself when he had toothache. With bleeding he combined purgation by seuna—"saigner et seigner." In addition, he used those materials contained in the pharmacopoeia of the day to which the Germans apply the term *Dreckapothek*. He supposed himself to be a follower of Hippocrates, Galen, and Fernel, in contrast with Arabian physicians, who had discountenanced excessive venesection. As chemistry began to emerge from alchemy Paracelsus and Van Helmont pushed forward the internal use of metallic compounds of

<sup>6</sup> *Kala-azar in Assam*. By T. C. McCombie Young, M.D., D.P.H., Lieutenant-Colonel I.M.S. With a foreword by Sir Leonard Rogers, C.I.E., M.D., F.R.S., I.M.S. (retired). London: H. K. Lewis and Co., Ltd. 1923. (Cr. 4to, pp. viii + 76; 4 plates, 7 charts. 7s. net.)

<sup>7</sup> *Guy Patin and the Medical Profession in Paris in the XVIIth Century*. By Francis R. Packard, M.D. New York: Paul B. Hoeber, Inc. 1925. (Extra post 8vo, pp. xxii + 334; 17 illustrations, including 9 full-page engravings. 4 dollars.)

mercury, antimony, and arsenic, which the ancients had employed merely in external conditions. They were dangerous remedies and no doubt gave rise to cases of poisoning. Patin attacked in particular the free use of vinum antimonialis as an emetic and sudorific; his attack failed, however, when the young Louis XIV recovered from an illness after being so dosed. For the same reason, that it was unknown to the ancients, he tried to prevent the introduction of cinchona bark, also of tea and coffee, then prescribed medicinally. He likewise opposed the administration of opium, mainly because Paracelsus had, so it seems, used what we call laudanum, as distinguished from succus papaveris, although there is some confusion over laudanum and hadanum—the resin with a volatile oil, acting as a stimulant and expectorant. The Paris Medical Faculty was then at the lowest stage of its history, and any influence which Patin may have exerted was in prolonging the practice of bleeding, which continued in France until after the Revolution. As a follower of Riolan he opposed Harvey's discovery, whereas the surgeons of Saint-Côme favoured the development of the discoveries in anatomy, physiology, and chemistry, which were to lead on to the memoirs rendering famous the Académie des Sciences and the Académie de Chirurgie in the eighteenth century. What Molière put in the mouth of Dr. Diafoirus in praise of his son can be said of Guy Patin: "But, above all things, that which pleases me in him, and in which he follows my example, it is that he attaches himself blindly to the opinions of our ancestors, and that he has never wanted to understand nor listen to the reasons and experience of the pretended discoveries of our time concerning the circulation of the blood and such like stuff."

### NOTES ON BOOKS.

The first volume of *The Early History of Veterinary Literature and its British Development*, by Major-General Sir FREDERICK SMITH, K.C.M.G., F.R.C.V.S., was concerned with the period down to 1700. The second,<sup>8</sup> which has now been issued, deals mainly with the eighteenth century and ends with the opening of the first English veterinary college; the author promises a third volume. The second volume provides at a most opportune time an excellent summary, written with a due sense of perspective. It affords complete and convincing evidence of the early interest taken in the veterinary art by the practitioners of human medicine—although that interest did not always obtain the success hoped for by the pioneers. The veterinary profession came into being with the establishment of the London College, which owed its origin in large measure to the efforts of the great John Hunter; there is little doubt that but for his death two years later its scientific advancement and that of comparative medicine in general would have been much more rapid. In addition to the work of Hunter, about thirty other physicians and surgeons wrote on veterinary subjects—a surprisingly large number when it is remembered that medical men of that period feared to incur professional degradation by contact with the diseases of the lower animals. Their work, however, was often marred by a lack of knowledge of the subjects with which they were dealing. Sir Frederick Smith is to be congratulated, not only on the writing of a most educative volume (it is founded on articles contributed by him to the *Veterinary Journal*), but also on directing the attention of the medical profession to a fertile source of information. The book is well printed and well bound and reflects the greatest credit on the publishers.

*The Art of Feeding the Invalid and Convalescent*<sup>9</sup> is a new edition of a little book which will be useful to matrons, nurses, and all who have the care of an invalid. It is written by a medical practitioner and a woman teacher of cookery. The editor, JESSIE J. WILLIAMS, justifies the publication of such a book by stating that "two thirds of all disease is brought about by error in diet." The choice of diets and the cooking thereof advised in the book are based on scientific investigation, and therefore welcome. The book consists of two parts: the first deals with general considerations upon food, and the second contains recipes arranged alphabeti-

cally and labelled "invalid" or "convalescent." The diet and also the preparation of the food are described for the following illnesses: acute febrile diseases, with special mention of typhoid fever; diabetes; and tuberculosis. The food indicated during chronic diseases is carefully dealt with, special mention being made of gout, constipation, liver and kidney diseases, and corpulence. The short chapter on infant feeding is on the whole excellent, although one of the reasons given for artificial feeding, that the breast milk is not agreeing with the infant, is now generally discarded. There is a brief but very helpful chapter on suitable diet for aged people.

We welcome the appearance of the first volume of the *Practical Medicine Series* (1924),<sup>10</sup> which, like its predecessor (see JOURNAL, July 12th, 1924, p. 59), is devoted to general medicine and divided into four parts under the same editors as in the previous year. An excellent account of recent work in infectious diseases and endocrinology is provided by Dr. George H. Weaver. Diseases of the chest, excluding the heart but including a section on tuberculosis, are discussed by Dr. Lawrason Brown, who pays special attention to x-ray diagnosis and recent methods of treatment of pulmonary tuberculosis. Dr. Robert B. Preble deals with diseases of the blood and blood-forming organs and the diseases of the blood vessels, heart, and kidneys, and emphasizes the importance of recent work on the social aspects of heart disease, subacute and recurrent endocarditis, and the various kidney function tests. Dr. Bertram W. Sippy and Dr. Ralph C. Brown review the recent literature of diseases of the digestive system and metabolism, as well as diseases of the liver and gall bladder. The volume, which is well printed and illustrated, is a worthy representative of a useful series.

The Hon. T. R. ST.-JOHNSTON, lieutenant-colonel, barrister-at-law, with medical qualifications, is a versatile person who has served under the Local Government Board and the Colonial Office, has held appointments in the Falkland Islands and in Fiji, and was a D.A.D.M.S. in the army in France. He is also the author of books of poetry, travel, ethnology, biography, and fiction. His book on *The Lau Islands* (Fiji) was reviewed in our columns of October 19th, 1918 (p. 434), and his latest novel *Pearl of Fortune*<sup>11</sup> also refers to the Fiji Islands. It is a story of the finding on an uninhabited coral reef of a pearl of immense size and value. On the violent death of the finder the pearl comes into the charge of the hero of the tale, whose duty it becomes to deliver the pearl to the dead man's daughter in England. After many temptations and dangers, during which two other men are killed, he succeeds in handing the jewel to the daughter, who is promptly robbed of it by the villain of the story. Colonel St.-Johnston is perhaps better at describing scenery than in the delineation of character. The hero is the most priceless ass to be placed in charge of a priceless pearl that we have ever met; after doing his best on innumerable occasions to lose the pearl he has the audacity to rebuke the girl for not putting it in a safer place! Our interest, however, in the hero's erratic proceedings was well maintained, and the book is quite good reading for a railway journey.

<sup>8</sup> *The Practical Medicine Series*. Under the general editorial charge of Charles L. Mox, A.M., M.D. Vol. I—General Medicine. Series 1924. Chicago: The Year Book Publishers, 1924. (Cr. 8vo, pp. 736; 32 plates. 3 dollars per volume; 15 dollars set of 5 volumes.)

<sup>11</sup> *The Pearl of Fortune: A Tale of the South Seas*. By T. R. St.-Johnston. London: Selwyn and Blount, Ltd. 1925. (Cr. 8vo, pp. 261. 7s. 6d. net.)

### PREPARATIONS AND APPLIANCES.

#### *Gadus Jelly.*

GADUS jelly is a preparation of cod-liver oil designed to disguise the taste which most persons find objectionable. Gadus cod-liver oil is prepared very carefully from fresh cod livers; it has only a slight flavour, but the vitamin content is high. The jelly, which has now been put on the market, contains 30 per cent. of cod-liver oil, but by the skilful admixture of other harmless constituents and by the use of a few flavouring agents the makers have succeeded in masking the fishy flavour. The preparation should be very valuable for administration to children who object to taking cod-liver oil. It is marketed in this country by Heyerdahl Products Co. (England), Ltd., 36, Regent Street, Cambridge.

#### *A Night Trap for Gnats, Mosquitoes, and Tsetse Fly.*

Dr. F. W. Alexander, medical officer of health for Poplar, has designed a simple device to trap insects which fly by night. In the centre of a wooden base a well protected night-light, or electric bulb, is fixed. This is surrounded by vertical sheets of ground glass arranged in wooden sockets so as to be placed in any desired position. The glass sheets are smeared with honey, or some other sticky substance, which can easily be washed off and replaced. The whole apparatus can be fixed on a pole and placed where the insects are most likely to be found. Dr. Alexander points out that this device can be made for a few shillings, apart from any storage battery or accumulator if an electric lamp is used.

<sup>9</sup> *The Early History of Veterinary Literature and its British Development*. Vol. II, The Eighteenth Century. By Major-General Sir Frederick Smith, K.C.M.G., C.B., F.R.C.V.S. Reprinted from the *Veterinary Journal*, 1923-24. London: Baillière, Tindall and Cox. 1924. (Roy. 8vo, pp. viii + 241. 15s. net.)

<sup>10</sup> *The Art of Feeding the Invalid and Convalescent*. New edition, thoroughly revised and brought up to date by Jessie J. Williams, M.C.A. London: The Scientific Press, Ltd. 1923. (Cr. 8vo, pp. 213. 4s. net.)

# British Medical Journal.

SATURDAY, FEBRUARY 7TH, 1925.

## THE MALIGNANT CELL.

DR. A. CARREL, of the Rockefeller Institute for Medical Research, New York, who delivered an address on the bearing of tissue culture on pathological problems at the Annual Meeting of the British Medical Association at Bradford last year,<sup>1</sup> has made an important contribution to the knowledge of a peculiar proliferation found in some fowls and known as the Rous sarcoma.<sup>2</sup> In this disease, where sarcoma-like growths are found, a filterable virus can be obtained which, on inoculation into other domestic fowls, reproduces similar growth-like structures. The nature of the condition has been the subject of much dispute, but the general opinion is that it is not a true malignant neoplasm. At any rate, the virus is active only for certain breeds of fowls and not for other animals, and; further, no such virus can be obtained from the true sarcomata of mammals.

When fragments of this fowl "sarcoma" are grown *in vitro* several kinds of cells proliferate—leucocytes, macrophages; and fusiform cells. In which of these does the virus reside? On growing the various cells in pure culture Carrel found that the fibroblasts were not malignant, while the macrophages when grafted into fowls invariably gave rise to tumours which grew rapidly and killed the animals. Going further, Carrel obtained pure cultures of large mononuclear cells by cultivating a film of white blood corpuscles, presumably from normal fowl blood (though this is not stated): three varieties of leucocytes emerged—large mononuclears, polymorphonuclear leucocytes, and endothelial leucocytes—but after two weeks' growth all had disappeared from the cultures except the large mononuclears. These grew singly and never formed tissue. To these pure cultures the filterable virus of the Rous sarcoma was added, and when the infected cells were introduced into chickens rapidly growing "tumours with metastases" resulted. In some experiments the monocytes cultivated *in vitro* migrated and multiplied for several weeks in their normal manner; their cultural properties remained unaltered, and the medium was not digested, but, nevertheless, tumours were produced by the injection of these monocytes into chickens. These tumours as a rule appeared later and grew less rapidly than with those cultures in which marked morphological changes had taken place in the cells. In most of the experiments, however, after three or four days a more specific change occurred in the infected monocytes: the cell protoplasm became granular and very vacuolated, the cell shape more or less rounded, and the rates of migration and multiplication in the medium were decreased. A few cells became agglutinated in dark clumps, which later increased in size and brought about digestion of the medium. The monocytes disappeared progressively from the coagulum, and from the masses of amorphous tissue these migrated large triangular, polygonal, and spindle-shaped cells, with sharp processes and a cytoplasm filled with granules; some cells assumed the appearance of normal fibroblasts. The digestion of the medium proceeded actively and led eventually to the destruction of all the

living elements. When chickens were inoculated with a small amount of the clear supernatant fluid of these cultures "malignant tumours" were as a rule developed in a short time.

Carrel concludes that the penetration of the Rous virus into large mononuclear leucocytes gave them the property of secreting the virus and caused them to die prematurely, though it probably did not for some time interfere with their reproductive power. It also rendered them capable of digesting the culture medium and assuming the appearance of fibroblasts, though these last properties are perhaps due to the formation of necrotic tissue by the dead monocytes. The "malignant" monocyte differs from the normal in being a diseased cell which is short-lived.

The Rous virus in a fowl is destroyed in a short time unless taken up by a tissue macrophage or monocyte. The infected cell multiplies and infects other macrophages, although it eventually dies; then the dead macrophages attract normal macrophages which become similarly modified. Carrel imagines that during this process growth-promoting substances contained in the macrophages are set free, and bring to the fibroblasts and other cells of the neighbouring tissues the food material and stimulus necessary for multiplication, though he produces no evidence for this theory. Since the Rous agent propagates itself within the cells, this process can continue indefinitely, and hence the tumour grows without limit in size.

Carrel's view is that whether this explanation of the mechanism of the growth of the Rous sarcoma prove to be strictly true or not, yet the difference between a normal and a "malignant" cell can be accurately analysed by this method. The tumour cell in this experiment appears as a diseased monocyte which propagates the Rous agent, degenerates slowly, and eventually dies. In the growth of Rous sarcoma the macrophages would appear to possess a function quite opposed to the duty previously attributed to them of defending the organism against bacteria and foreign substances. They appear rather to protect the active agent of the Rous sarcoma against destruction by the body fluids, and to supply the conditions necessary for its propagation.

The whole observation constitutes a welcome addition to our knowledge of an obscure subject. Carrel undoubtedly accepts the view that the condition is a sarcoma. The histological appearances constituted the most important argument for the neoplastic nature of the process: otherwise it would have been dismissed as an infective granuloma. These fusiform cells were the outstanding feature that stood in the way of the latter view. Carrel may not have appreciated the fact that his observation—namely, that the virus resides in the leucocytes and not in the connective tissue cells—has now given the critics a particularly strong argument for their view that the Rous sarcoma (which differs in many respects from true sarcomata) is not a malignant growth at all, but a granuloma with marked stromal reaction. But such is the result.

## TESTS FOR HEPATIC EFFICIENCY.

SEVERAL questions naturally arise in connexion with any functional test for hepatic efficiency. One is, How far does a test for one function—for example, in the case of phenoltetrachlorophthalein test for the antitoxic function—throw light on the condition of the other hepatic functions? Another is, To what extent does the reserve power and compensatory hyperplasia of the liver in chronic cases enable its functions to be so well carried out that efficiency tests give a normal

<sup>1</sup> BRITISH MEDICAL JOURNAL, July 26th, 1924, p. 140.

<sup>2</sup> Journ. Amer. Med. Assoc., January 17th, 1925, p. 157.

result although there is structural change obvious to ordinary physical examination? A third question, which amounts to much the same as the second, is, How much can be expected from tests in chronic hepatic disease as compared with their results in acute disorders? A fourth is, What is the relative value of the various tests?

Piersol and Bockus,<sup>1</sup> in their comparative studies in liver function by some of the later methods, bear on some, especially the last, of these questions. Comparison of the Rosenthal modification of the phenoltetra-chlorophthalein test with the urobilinuria method, Vidal's haemoclasie crisis test, and the duodenal tube method of applying the phenoltetra-chlorophthalein test, showed that the Rosenthal modification was more delicate than the urobilinuria test, and that the haemoclasie crisis method was unreliable and often at variance with the other tests used as a means of estimating hepatic efficiency. A similar opinion, it may be mentioned, has been expressed by others (Lepehne, Gerrard). In jaundice due to treatment of syphilis by arsenobenzol compounds Rosenthal's test showed a well marked disturbance of hepatic function, and they conclude that there is probably some degree of liver dysfunction present in practically all patients with syphilis who are undergoing this form of treatment. Rosenthal, in a companion paper,<sup>2</sup> found that while his test gives negative results in the primary and tertiary stages of syphilis, the test is positive in the secondary stage, and especially when employed early in the jaundice following treatment by arsenobenzol. By means of the test the severe damage present at an early stage could be watched into convalescence of the liver cells. These results of Piersol and Bockus and of Rosenthal are, it will be noted, in accord with Surgeon Commander W. I. Gerrard's investigations by means of the van den Bergh test on the frequency of degenerative changes in the hepatic cells, as shown by latent jaundice, or disturbance of the biliary function, in syphilitic patients undergoing treatment by arsenobenzol compounds.<sup>3</sup> Piersol and Bockus did not compare the results of the laevulose tolerance test, which in the hands of others has given many similar results, with those of Rosenthal's modification of the phenoltetra-chlorophthalein test. They state also that every case of diabetes mellitus thus tested by the "tetra-chlor" methods has provided them with some evidence of hepatic disturbance, thus showing that more than one of its functions was disturbed.

In catarrhal jaundice Rosenthal found evidence of severe disturbance of hepatic function, thus supporting the now widespread view that there is a hepatitis rather than a catarrhal swelling of, with a plug of mucus in, the lower end of the common bile duct. On the other hand, in ordinary hepatic cirrhosis the evidence of disturbed hepatic function was usually slight, and the argument that compensation had taken place is supported by the citation of a case with obvious hepatic enlargement from a healed gumma in which the test showed a normal result. Ottenborg, Rosenfield, and Goldsmith<sup>4</sup> have employed Rosenthal's method, and regard it as valuable as a means of detecting early cirrhosis, secondary growths, and chronic venous stasis (cardiac) of the liver.

The phenoltetra-chlorophthalein test was employed in the toxæmia of pregnancy by Rosenfield and Schneiders in 1923, and more recently by Judson A.

Smith<sup>5</sup> of Boston, Massachusetts, who tried it at the same time on twenty normal pregnant women and forty-four cases of toxæmia characterized by albuminuria and high blood pressure, including eight patients with chronic nephritis and seven with convulsions. The pregnant women on whom control observations were made gave results that may be regarded as being within the limits of the normal. About half the toxæmic cases showed abnormal retention of the dye, and in this group well marked albuminuria and severe symptoms, including convulsions, were more frequent, and the mortality was higher than in the group of cases with a normal test, which, it should be noted, included most of the patients with chronic nephritis. In the four fatal cases in which the test was abnormal some damage to the liver was found, but the degree of retention of the drug did not appear to be a trustworthy index of the amount of necrosis of the liver. In the discussion at the Royal Society of Medicine a year ago on the toxæmias of pregnancy—introduced by Comyns Berkeley, E. C. Dodds, and A. L. Walker—among other tests, those for hepatic efficiency were considered; and O. L. V. de Wesselow said that as the laevulose tolerance test had given conflicting results in eclampsia it was of little practical value.<sup>6</sup>

It may be convenient to refer briefly to the history of the phenoltetra-chlorophthalein test. It dates from 1909, when J. J. Abel and L. G. Rowntree showed that this dye, prepared in the previous year by Orndorff and Black, was removed from the blood by the liver only. The efficiency of that organ to excrete the dye in the bile was first investigated by examination of the faeces (Rowntree and Whipple), and later of the duodenal contents removed by a tube (McNeil, Aaron, Horsley Gantt, and others). But in accordance with the general tendency to go, so to speak, to the fountain head and to examine the blood rather than the excretions, Sanford M. Rosenthal in 1922 studied the blood content of experimental animals and man after the intravenous injection of phenoltetra-chlorophthalein; in healthy human beings the blood serum is almost entirely clear of the dye one hour after the injection of an amount equivalent to 5 milligrams per kilogram of body weight; when the liver is damaged the amount of dye remaining in the blood provides a quantitative index of the degree of impaired function. An obvious advantage of Rosenthal's modification of this test is that it can be employed when there is complete obstruction to the passage of bile into the intestine, and in his recent paper Rosenthal shows that in the early stages of obstructive jaundice the liver cells, while not damaged, can take up the dye from the blood, although it cannot be excreted in the normal manner through the biliary system, and this is confirmed by Bloom and Rosenau.<sup>7</sup>

The dye is practically non-toxic. But Bloom and Rosenau consider that the high incidence of thrombosis and of other untoward reactions after its injection is a serious objection to its clinical use. In the course of one hundred tests Judson A. Smith had two general reactions, and he mentions that thrombosis of the injected vein was fairly frequent; Rosenthal records four cases of thrombosis and observes that induration of the vein was rather common among one hundred and fifty cases; Piersol and Bockus, who noticed thrombosis of the vein five times among sixty-seven injections, believes that the incidence of this drawback

might be obviated by the injection of a quantity of the dye smaller than that employed by Rosenthal. From the patient's point of view—objection to the intravenous injection of coloured fluid and the risk of thrombosis—Boardman and Schoonmaker, after comparison of the two methods, prefer the use of the duodenal tube to Rosenthal's modification.<sup>5</sup> It may be added that Rosenthal, in association with E. C. White, has found that bromsulphalein (phenoltetrabromphthalein sodium sulphonate), when similarly employed, gives much more sharply cut results in the estimation of hepatic efficiency than does phenoltetrachlorphthalein, and these workers propose to issue an early report on the standardization for the clinical use of this new dye. Delprat, Epstein, and Kerr<sup>6</sup> have recently employed rose bengal di-iodotetrachlorfluoresceine, of the triphenylmethane series, in the same manner, and obtained much the same results as did Rosenthal with phenoltetrachlorphthalein.

#### GOLD TREATMENT OF TUBERCULOSIS.

Our previous references<sup>1</sup> to Professor Holger Moellgaard's new method of treating tuberculosis by an inorganic compound of gold and sodium, together with an antidotal serum, may now be supplemented by an account of two papers appearing in recent issues of the Danish medical journal *Ugeskrift for Læger*.<sup>2</sup> The first of these, by Professor Moellgaard, deals with the experimental basis of the treatment. His investigations, he says, were inspired by the observation made by Koch, and published as long ago as 1890, that a salt of gold inhibits the growth of tubercle bacilli in a solution as weak as one in a million. Turning to the researches of Feldt and Spies, and the gold preparation, "krysolgan," introduced by them in 1917, the author points out that the successes achieved by this drug dwindled as the dose. After describing the properties and chemical formula of his own preparation, "sanoerysin," and stating that it materially checks the growth of tubercle bacilli in a solution of one in a million and completely arrests it in a solution of 1 in 100,000, he gives a detailed account of experiments with such animals as guinea-pigs. Subcutaneous injections of tubercle bacilli were given, and the site of inoculation was then infiltrated with sanoerysin. All the control guinea-pigs developed generalized tuberculosis, whereas some of the animals treated by sanoerysin remained free. While the treatment of a tuberculous animal with sanoerysin provoked a violent reaction similar to, and probably identical with, the shock caused by a large dose of tuberculin given to a tuberculous animal, reaction could be avoided or overcome by an injection of serum obtained from a tuberculous animal, which appeared to neutralize the toxins generated by the interaction of sanoerysin with tubercle bacilli in the body. In other words, passive immunity was conferred on the tuberculous animals, which were thus protected from the otherwise fatal action of sanoerysin. These observations suggest that the action of sanoerysin depends on its capacity to destroy tubercle bacilli in the body. The reaction of the tuberculous animal possessing natural or passive immunity to sanoerysin differed greatly from the reaction of the tuberculous animal not possessing such immunity; the immunized animal reacted with fever, a rash, loss of weight, and diarrhoea, while the non-immunized animal reacted with a fall of temperature, albuminuria, myocarditis, and oedema of the lungs. Thera-

peutic doses of sanoerysin given to a non-tuberculous animal had no ill effects, whereas the same doses given to tuberculous animals gave rise to all the reactions that would be expected of a process entailing the wholesale destruction of tubercle bacilli in the tissues. After treatment with sanoerysin had been continued for some time and clinical recovery had been achieved, the ex-tuberculous animals ceased to react to sanoerysin. The second paper, by Dr. K. Secher, describes early clinical tests with sanoerysin. In this it is stated that by November, 1923, Moellgaard's experimental work with sanoerysin in tuberculous and non-tuberculous animals had proceeded so far that clinical tests on human beings had become justifiable. Since then Secher has given sanoerysin to a considerable number of hospital patients, but the choice of patient and the dose of the drug were at first faulty from lack of experience. The three principal reactions—fever, rash, and albuminuria—acted as guides to the conduct of each case. The temperature in particular was a valuable index to the response of the tuberculous body to the intravenous injections of sanoerysin. As the tests proceeded it became more and more evident that cases in which difficulties were anticipated required preliminary treatment to avoid the albuminuria which was liable to ensue after injections of sanoerysin. Serum from a tuberculous animal was given by intramuscular injection in doses of 20 to 40 c.cm., and proved potent in counteracting the "tuberculin shock" caused by the sanoerysin. It was found advisable to continue the injections till there was no longer any reaction to them. Of the 9 patients who died, and whose death was directly connected with the treatment, 2 died from shock, 3 from Herxheimer's reaction, 3 from poisoning with emesis and hiccup, and 1 from cachexia. Of the 12 slight cases of pulmonary tuberculosis, 3 of which were sputum-positive, all were discharged as symptom-free, but this was the case with only 2 of the 21 severe cases. All the slight cases, which became symptom-free under treatment, reacted violently, severe erythema being sometimes provoked. With further experience the author has been able to give sanoerysin to patients whom at first he thought unsuitable for it. It seems to be very effective for the chronic fibrotic cases; areas of consolidation in the lungs clear up, rales disappear, and certain patients have been able to return to work. Of 3 patients suffering from miliary tuberculosis, 1 was discharged as much improved, and 1 as cured. Tuberculous pleuritis also responded very satisfactorily; of the 12 cases of acute pleurisy treated, 11 were discharged as symptom-free. The treatment could be given to children provided it was instituted early enough, and Dr. Secher expects that the early treatment of glandular tuberculosis in childhood will avert the development of the later stages of tuberculosis. But the difficulties and the dangers of the treatment render it, for the present at least, suitable only for hospital practice.

#### A NEW MOTOR DANGER.

Reports from America show that commercial enterprise has evolved a wholly new danger to the general public. Some time ago the research staff of the General Motors Company discovered that the addition to petrol of one part in a thousand of the heavy volatile fluid lead tetra-ethyl ( $Pb(C_2H_5)_4$ ) was an efficient method of preventing knocking in motors. This is a discovery of first-rate commercial importance, for it is said that it may result in a saving of 25 per cent. of petrol, and also may make possible the use of high compression petrol engines. A new form of petrol has been placed on the market in America termed ethyl gasoline, which contains 1 per 1,000 lead tetra-ethyl, together with organic chloride and a distinctive dye. This mixture is harmless in theory, since the organic chloride reduces the lead tetra-ethyl, and lead

<sup>1</sup> Boardman, W., and Schoonmaker, G. D.: *Amer. Journ. Med. Sci.*, Philadelphia, 1924, clxviii, 688.

<sup>2</sup> Delprat, G. D., Epstein, N. W., and Kerr, W. J.: *Arch. Int. Med.*, Chicago, 1924, xxxiv, 533.

<sup>3</sup> *BRITISH MEDICAL JOURNAL*, November 8th, 1924, p. 870; November 22nd, 1924, p. 861; January 24th, 1925, p. 176.

<sup>5</sup> *Ugeskrift for Læger*, December 25th, 1924, p. 1035; January 1st, 1925, p. 1.

chloride appears in the exhaust. The United States Bureau of Mines<sup>1</sup> made experiments on the subject, and found that animals did not suffer in health when exposed for eight months to a definite concentration of exhaust gas from an engine using ethyl gasoline. Unfortunately these comforting conclusions do not take into account all the practical dangers. In the first place, serious trouble has been experienced in the manufacture of lead tetra-ethyl, and in one factory alone there were five deaths and forty-four other cases of serious poisoning. This is not surprising, for organic lead compounds of the type of lead tetra-ethyl have long been known as the most dangerous of metallic poisons; they are, indeed, only rivalled by the corresponding mercury compounds. A few milligrams of lead tri-ethyl are sufficient to produce in a medium-sized dog convulsions similar to those caused by strychnine.<sup>2</sup> Lead tetra-ethyl is one of the comparatively few substances which can be absorbed rapidly through the skin; moreover, it is volatile, and can be absorbed still more rapidly through the lungs. Like all lead compounds, it is a cumulative poison, but it produces a train of symptoms quite distinct from those of inorganic lead poisoning. The initial symptoms are insomnia, nausea, loss of weight, anaemia, and low blood pressure. In severe cases acute delirium resembling delirium tremens occurs. There appear to be many possible dangers in distributing a poison of this nature in large quantities throughout the community. The chief danger lies in its use in garages, since there is always the risk that petrol may be spilt; moreover, cars while being started discharge unconsumed exhaust, and in either case lead tetra-ethyl will be set free in confined spaces. There seems to be only a remote chance of unconsumed lead tetra-ethyl producing poisoning in the public streets; but, on the other hand, we doubt if the health of the community would be benefited by having considerable quantities of lead chloride sprayed continually into the chief streets of our large towns in the form of a fine dust. The amount of inorganic lead required to produce chronic poisoning is only a small fraction of a grain a day, and it would probably take many months before the full effects of cumulative poisoning with minute quantities of lead would become manifest. For the above reasons the proposed introduction of ethyl gasoline appears to be a large-scale pharmacological experiment of a dangerous nature, which might possibly produce disastrous results in the community. We understand that the City of New York has forbidden the use of ethyl gasoline in its area, and it is to be hoped that similar action will be taken in this country.

#### THE SHAPE OF THE SKULL.

A LECTURE on "The cause of skull shapes" was delivered by Dr. Arthur Robinson, professor of anatomy in the University of Edinburgh, under the auspices of the Royal Anthropological Institute, in the rooms of the Geological Society, Edinburgh, on January 19th. He drew attention to the fact that the cranial and facial parts of the skull varied in shape and size at different periods of life, and that it was now generally admitted that the size of the cranial part depended on the amount of its contents. Since in normal circumstances these contents were mainly brain, it followed that the size of the cranium depended on the size of the brain. On the other hand, the cause of the shape of the cranium was still a matter of dispute, and a satisfactory explanation had to account, not only for differences in proportion, but also for the formation of localized expansions which were numerous and varied. The two main factors which might be assumed to have effect on cranial shape were environment and heredity. Environment might be considered to include the associated effects

of climate and altitude and the immediate environment of the muscles attached to the skull bones. With regard to general environment, there was a fairly common idea that a special type of head was being evolved in America, but there was no definite proof that such was the case. It seemed impossible to avoid the conclusion that the shape of the skull depended mainly upon hereditary tendencies which worked under the law of genetic control. If that was the case, then the shape of the cranium depended upon the growth of the brain, and the growth of the brain was undoubtedly governed by the laws of heredity.

#### IODIZED TABLE SALT.

THE brilliant work of Marine and his colleagues, who have proved that simple goitre is a preventable disease, has led to the consideration of the best way of supplying iodine to communities where goitre is frequent. Marine and Lenhart have shown that 2 grains of sodium iodide given daily for a fortnight every six months prevents goitre in school children. This represents a total of 56 grains (3.6 grams) a year. Klinger in Zürich has shown that 5 mg. of iodine given weekly throughout the year is equally efficient for school children. This represents a total of only 4 grains (0.26 gram) of iodine a year. Marine has pointed out that the thyroid has only limited means of storing iodine, and that therefore the most economical method of administering iodine is to give it in small doses as frequently as possible. He considers that the body requires about 2 grains (0.13 gram) of iodine a year if the iodine is given continuously in minute quantities. This figure agrees with such knowledge as we have of the amount of thyroxin consumed daily by the body. Any method of giving iodine as a preventive of goitre should therefore aim at providing about 2 grains a year; it may be found that smaller quantities suffice, but this is the figure indicated by our present knowledge. The problem has been met in some American cities by adding iodides to the water supply. This, however, is an extremely wasteful method, as only a very small fraction of the water supplied to a town is used for cooking or drinking. Another method is to provide iodized table salt, and here we meet with the difficulty of determining how much ought to be added. The Swiss Goitre Commission recommended a total of 2 to 5 mg. of iodine per kilo of salt; and iodized table salts are now used extensively in Switzerland and the Tyrol. Salts are now being placed on the market in England which contain a quantity of iodine similar to that recommended by the Swiss Goitre Commission. We have received, for example, from Messrs. George Hamlett and Sons, Ltd., a sample of an iodized table salt, to which they have given the trade name "Premido." The only question seems to be whether its use as a table salt would provide a sufficient quantity of iodine. An individual on a normal diet excretes about 10 grams of sodium chloride a day. Less than half of this is taken as table salt, and therefore a content of 5 mg. of iodide in table salt per kilo of body weight would provide an individual with much less than 10 mg. (1/6 grain) of iodine a year. Marine<sup>1</sup> has recommended the use of table salt containing 0.2 per cent. iodine as a prophylactic in the districts where endemic goitre prevails to a mild extent. This is four hundred times the concentration recommended by the Swiss Goitre Commission. The idea of supplying iodine to the population by adding iodides to table salt appears to be a reasonable proposal, but before this method is used and relied upon as a prophylactic it would seem desirable that the authorities should agree within the nearest power of ten as to the proportion of iodine necessary. Another important question which arises is whether persons with fully active thyroids are likely to suffer if supplied regularly with an excess of iodine. Marine and Klinger both

<sup>1</sup> Quoted in the *Journ. Amer. Med. Assoc.*, 1924, 83, 1511.  
<sup>2</sup> Mason: *Journ. Lab. and Clin. Med.*, 1921, 6, 427.

<sup>3</sup> *Proc. Inst. Med. of Chicago*, 1924, pp. 31-46.

say that they have watched carefully for exophthalmic goitre, and have found no evidence that it is produced by large-scale prophylactic iodine medication. Sir William Macpherson has, however, reported, in a letter published in our columns of January 17th, that this danger is still under consideration in Switzerland.

#### INTERNATIONAL CONGRESS OF RADIOLOGY.

ARRANGEMENTS are being made by the Electro-Therapeutic Section of the Royal Society of Medicine, the Röntgen Society, and the British Institute of Radiology, to hold a Congress of Radiology in London from July 1st to 4th. The president of the congress will be Mr. C. Thurstan Holland, Ch.M., of Liverpool. Radiologists from all countries are invited to take part, and it is hoped to arrange for the formation of a comprehensive international committee and the establishment of a full international congress at stated intervals in different countries. It is further hoped that at this London congress arrangements will be made for the first International Congress, and that the date of this and the country in which it will be held will be decided by the international committee. Physics, electro-therapeutics, and allied subjects will be included in the scope of the London congress, and all papers to be read should be sent to the Secretary-general, at the British Institute of Radiology, not later than May 1st, accompanied by a short abstract. The organizing committee states that it is particularly desirable that papers, wherever possible, should be approved by a recognized society of which the author is a member. All papers and abstracts must be typewritten or printed. Each paper will be read at the congress in the language selected by the author, and it is intended to publish the papers read in the *British Journal of Radiology*. In connexion with the congress there will be an exhibition of radiological and electrical apparatus, and of radiograms. Radiological and electro-therapeutic societies are invited to send approved representatives who shall be eligible to serve on the international committee. Societies are requested to bring the congress to the notice of their members and to secure the attendance of as many as possible. The fee for membership of the congress will be 2 guineas, and it is hoped that all who wish to attend will signify their intention as soon as possible so that some numerical estimate may be possible. Arrangements for travelling facilities and hotel accommodation are being made. The opening meeting of the congress will be held on the morning of Wednesday, July, 1st, and on the previous evening a reception will be held so that delegates and members may meet. The house of the British Institute of Radiology (32, Welbeck Street, London, W.1) will be the administrative centre for the congress, and an information bureau, with interpreters, will be provided. All communications should be addressed to the Secretaries, International Congress of Radiology, c/o the British Institute of Radiology.

#### ASTIGMATIC CORRECTION FOR NEAR WORK.

In the *British Journal of Ophthalmology* for January is published a paper by Mr. A. S. Percival on the "alteration of the power of a cylinder when used for near work." The mathematics of this paper may not be to the liking of the majority of readers, but the point is a very pretty one, and deserves the attention of all who have to prescribe spectacles. Mr. Percival finds that in the higher cylindrical powers, if the correct glass be given for distance, it will not accurately correct the astigmatism for near work as well. The corneal astigmatism is fixed. Mr. Percival finds that a cylinder of approximately 9 per cent. higher

strength will be required to correct the astigmatism fully when used for work at a distance of about 30 cm. from the glasses. If a full presbyopic addition of +3D be given, no further addition is required, because the 3D addition may be regarded as simply making the divergent rays from the close work become a parallel beam. If a partial correction for presbyopia be given, a smaller addition to the cylindrical lens will be needed. The following examples will make the matter clear. If no presbyopic correction be given, increase the cylinder by 9 per cent.; if +1 correction, increase by 6 per cent.; if +2, increase by 3 per cent.; if +3, do not increase the cylinder. This is a point of practical importance in dealing with the higher cylindrical lenses. If no presbyopic addition be given, 5.5D of astigmatism at a distance will require 6D (6.00SD) for reading; but 1D of astigmatism at a distance would be corrected by a 1.09D cylinder for near work, and this addition is, in practice, negligible. The paper ends with a discussion of an interesting point about intorsion of the eyes when converged and depressed; the part played here by the superior oblique muscles in the depression of the eyes may lead to a variable amount of intorsion; if this occurs, the axes of the cylinders should be intorted also. A valuable table gives in the second and fourth columns the lenses that should be used for close work, if exactly the same correction is required as that for distance, which is supplied in the first and third columns.

#### RAINFALL IN 1924.

THE general impression that 1924 was a very wet year in England and Wales is fully borne out by the report of Mr. F. J. W. Whipple, superintendent of the British Rainfall Organization, Meteorological Office (*Times*, January 30th). It was the wettest year since 1912. Taking the average fall at 100, it was 121 in 1924 and 125 in 1912. The year 1903 was wetter (128). The excess of rain in Ireland was last year a little greater (122 per cent.) than in England and Wales, and in Scotland considerably less (105). Taking the British Isles as a whole the percentage was 117, as compared with 127 in 1903. These percentages, however, while they justify the impression mentioned, give no idea of the actual amount of precipitation. Thus, while in England last year it was 39.6 inches, as compared with an average for 1881 to 1915 of 32.7, in Wales it was 60.8 compared with 50.1, in Scotland it was 52.8 compared with 50.3, and in Ireland 52.8 compared with 43.3. The wettest station in the British Isles, Glenquoich in Inverness-shire, was a little less wet than usual, having 108.92 inches instead of its average of 110.75. The floods in the Thames valley, which began about Christmas, were due to a combination of circumstances. In the early part of the month there was little rain; in the second week, indeed, there was a very widespread fog. On December 15th there was heavy rain (0.69 inch in the Thames valley); then there was a spell of dry weather, but on December 23rd it began to rain in earnest, and before the end of the year 2.79 inches had fallen, or an average of 0.31 inch a day. As the river above the first lock (Teddington) can only dispose of about 0.2 inch of rain a day, any greater fall in the valley must either sink into the soil or overflow the channel. In the valley of a river flowing through an alluvial country there is, generally speaking, a constant downhill movement of water, not only in the bed of the river but through the subsoil of either bank. The water level in the soil varies directly with the amount of rain, but in an average season much of the water that falls in the valley is being gradually drained into the river by side streams. This year the soil, when the heavy rains came at the end of December, was already waterlogged. Mr. Whipple states that even at the Old Deer Park at Richmond (below locks) the under-

ground water was nearly 3 ft. higher in June than it had been at the end of March. After that each month, with the single exception of November, showed an excess of rain. It was especially in the South of England that the rainfall of 1924 was above the average. At High Wycombe, in the Chiltern Hills, the figure for the year was 38.94 inches compared with an average of 25.90—an excess of 50 per cent. The river which drains this area empties into the Thames. The rainfall was unusually high also at Windsor (42 per cent. above the average). In some places in England thunderstorms caused heavy falls within short periods. Such storms occurred on July 22nd in a string of places on a line from Guildford to the Norfolk coast. The heaviest fall recorded was 4 inches at the Royal Horticultural Society's ground at Wisley, Surrey; at South Kensington  $1\frac{1}{4}$  inches fell in twenty-five minutes. There was another big storm in the north of London on July 29th, and at Hampstead, which was caught in both storms, the total fall for the month was 7.60 inches. Mr. Whipple gives a brief description of a storm which occurred in August near Bridgwater, between the Quantock Hills and the mouth of the River Parret. It was, he says, in some respects by far the greatest ever recorded in the British Isles. The rainfall measured at Cannington was no less than 9.4 inches, and of this amount the observer, Mr. Kendall, reckons that at least 8 inches fell in five hours. Such a rainfall would have done great damage in some parts of England, but the countryside affected was sparsely populated and well provided with brooks, so that the damage was minimized, though the roads suffered badly. As has been said, the earlier part of the year had been wet, so that the ground in many districts was sodden. April, normally one of our driest months, was wet (3.4 inches), making it with one exception (1878) the wettest April on record for Kew Observatory. May also had a very heavy fall all over the British Isles, yielding more than twice the average (214 per cent. in England and Wales). September too was wet (174 per cent. in England and Wales), so that the circumstances conspired to bring the floods which caused so much inconvenience, especially in the Thames valley at the turn of the year.

#### INFLUENZA.

Last week the deaths from influenza in the great towns of England and Wales increased from 142 to 195, and two cities outside London (which had 39 deaths) recorded 10 or more deaths—namely, Manchester 22 and Salford 10. The notifications of pneumonia suggest wide prevalence in the Midlands, Lancashire, and Yorkshire. The course of the mortality is very similar to that of last year, as will be seen from the following figures, the deaths in the corresponding week of last year being shown in parentheses: 100 (98), 124 (93), 142 (153), 195 (236). In 1924 the deaths continued to increase for another five weeks and attained a maximum of 730. It seems therefore probable that we have to do with a recrudescence of the same order of importance, and that the maximum mortality is not likely to exceed 700 or 800 in the great towns (with a population at risk of rather more than 19 millions). However, prophecy is more than usually rash in connexion with influenza.

From the full report printed at page 285 it will be seen that an application on behalf of Dr. P. Bateman for leave to appeal against his recent conviction and sentence for manslaughter was granted by the Court of Criminal Appeal on February 2nd, and it is understood that the hearing of the appeal will open on February 9th. The argument by Mr. Norman Birkett, K.C., counsel for the appellant, will be found of considerable interest.

## Nova et Vetera.

### MEDICAL MEN IN "SCENES OF CLERICAL LIFE."

THE characters in the three stories which collectively form *Scenes of Clerical Life*, by George Eliot, were, as is well known, drawn in the majority of cases from persons who were actually living in or near Nuneaton during her early years.<sup>1</sup> It is for this reason that the three stories in question occupy a unique position in English fiction. The characters include four medical men who practised in Nuneaton; they appeared as "Mr. Pilgrim," "Mr. Pilgrim's assistant," "Mr. Pratt," and "Mr. Brand" respectively. All were drawn from life, and all have been positively identified with the exception of the second, but, as will shortly appear, it is possible at least to suggest who he really was.

The first, "Mr. Pilgrim," was William Bucknill. He was born at Rugby in 1781, and was educated at Rugby School. In 1800, at the early age of 19, he obtained the diploma of M.R.C.S., and commenced practice in Nuneaton shortly afterwards. He lived in a house which stood in front of the site now occupied by the Post Office. During the year 1804, and probably for a still longer period, he was in frequent attendance upon Sir Roger Newdegate (1719-1806) of Arbury Hall (the "Cheverel Manor" of George Eliot), near Nuneaton, and also upon the household, as appears from an account of that year for his professional services now in the possession of Dr. E. N. Nason of Nuneaton. An interesting item on this account is a charge of £22 4s. for one hundred and forty-eight inoculations: this is doubtless a reference to the old practice of inoculating variola. Another interesting feature is the doctor's very reasonable fee: he charged Sir Roger half a crown for a "journey"—that is to say, for a visit. As Arbury Hall was at least two and a half miles from his home in Nuneaton this fee was certainly not excessive. It is eloquent testimony to Dr. Bucknill's ability that Sir Roger should have chosen him for his medical adviser, for the doctor was only 23 years of age at the time in question. Dr. Bucknill, after a long professional career, retired from practice during the middle fifties, and died after a prolonged illness on April 4th, 1860, aged 79.

His assistant ("Mr. Pilgrim's assistant") was probably Dr. Edward Nason (1800-1868), who studied at Guy's Hospital and became M.R.C.S., L.S.A. in 1822. He practised for some years in partnership with Dr. Bucknill. This partnership was in existence in 1831, although it was ultimately dissolved; and it is therefore possible that Dr. Nason entered the practice as an assistant with a view to partnership. This is the principal reason for identifying him with "Mr. Pilgrim's assistant," for the latter is mentioned by the novelist in terms which are too brief for positive identification.<sup>2</sup>

The third, "Mr. Pratt," was in real life Mr. Bond. There were for some years two practitioners of the latter name in Nuneaton. The eldest was J. Bond. He held no qualification, but his name appeared in the early medical directories (issued before the Medical Act came into force) because he had been in practice prior to 1815 (the date of the Apothecaries Act). He died on April 10th, 1849, aged 79. The other practitioner of the same name was William Hargreave Bond, L.S.A. 1828, who died about 1847. There seems, however, to be no doubt that "Mr. Pratt" was J. Bond. "Mr. Pratt" is stated by George Eliot to have been long established in "Milby" (Nuneaton), and of the two practitioners named Bond, the eldest, J. Bond, is the only one who can have answered this description during her childhood.

The fourth, "Mr. Brand," to whom only brief reference was made in the stories,<sup>3</sup> was Mr. Harris. He lived at Chilvers Coton (the "Shepperton" of George Eliot), near Nuneaton, and died in November, 1837, aged 39.

*Scenes of Clerical Life* contains long and amusing descriptions of "Mr. Pilgrim" and "Mr. Pratt." It is impossible to ascertain the precise extent to which these descriptions are coloured with humorous exaggerations, but there is little doubt that they were, in the main, faithfully drawn, even if an element of light and entirely friendly caricature is by no means lacking. As pen-pictures of two practitioners of the old school, by so acute an observer as George Eliot, they thus possess some historical interest, and no apology is needed for quoting

<sup>1</sup> Being part of a paper read before the Nuneaton and Tamworth Division of the British Medical Association, January 25th, 1924, by Richard J. Cyriax, M.R.C.S., L.R.C.P.

<sup>3</sup> *Janet's Repentance*, chapters xxii, xxiii.

<sup>4</sup> *The Sad Fortunes of the Rev. Amos Barton*, chapters vii, viii.

their principal features here. In the extracts which follow the novelist's own words have been adhered to as far as is possible.

Mr. Pilgrim was a large, tall, heavy man, who visited, on horseback, those patients of his who lived some distance away. He occasionally affected aristocratic airs, and gave late dinners with enigmatical side-dishes and poisonous port. He was never so comfortable as when he was relaxing his professional legs in one of those excellent farmhouses where the mice are sleek and the mistress sickly. He looked with great tolerance on all shades of religious opinion that did not include a belief in cures by miracle. On this point he had the concurrence of Mr. Pratt, the only other medical man of the same standing in Milby (Nuneaton). Pratt was middle-sized, insinuating, and silvery voiced.

He "elegantly referred all diseases to debility, and, with a proper contempt for symptomatic treatment, went to the root of the matter with port-wine and bark; Pilgrim was persuaded that the evil principle in the human system was plethora, and he made war against it with cupping, blistering, and cathartics. They had both been long established in Milby, and as each had a sufficient practice, there was no very malignant rivalry between them; on the contrary, they had that sort of friendly contempt for each other which is always conducive to a good understanding between professional men; and when any new surgeon attempted, in an ill advised hour, to settle himself in the town, it was strikingly demonstrated how slight and trivial are theoretic differences compared with the broad basis of common human feeling. There was the most perfect unanimity between Pratt and Pilgrim in the determination to drive away the obnoxious and too probably unqualified intruder as soon as possible. Whether the first wonderful cure he effected was on a patient of Pratt's or of Pilgrim's, one was as ready as the other to pull the interloper by the nose, and both alike directed their remarkable powers of conversation towards making the town too hot for him. But by their respective patients these two distinguished men were pitted against each other with great virulence. Mrs. Lowme could not conceal her amazement that Mrs. Phipps should trust her life in the hands of Pratt, who let her feed herself up to that degree, it was really shocking to hear how short her breath was; and Mrs. Phipps had no patience with Mrs. Lowme, living, as she did, on tea and broth, and looking as yellow as any crow-flower, and yet letting Pilgrim bleed and blister her and give her lowering medicine till her clothes hung on her like a scarecrow's. On the whole, perhaps, Mr. Pilgrim's reputation was at the higher pitch, and when any lady under Mr. Pratt's care was doing ill, she was half disposed to think that a little more 'active treatment' might suit her better. But without very definite provocation no one would take so serious a step as to part with the family doctor, for in those remote days there were few varieties of human hatred more formidable than the medical."

Pratt's patients were profoundly uninteresting to Pilgrim; their very diseases were despicable, and he would hardly have thought their bodies worth dissecting. But there was, at the same time, in Mr. Pilgrim's heart a latent store of tenderness and pity which flowed forth at the sight of suffering."

### PULMONARY TUBERCULOSIS TREATED BY SPAHLINGER'S SERUM.

In our issue of January 3rd (p. 43) we published an article under this title illustrated by reproductions of two radiograms. On October 30th, 1924, we had received from M. Spahlinger (Carouge, Geneva) a letter transmitting the reports of Dr. Stephani and Dr. Hudson. A proof of the article was sent to Dr. Stephani and returned by him unaltered. The proof was received here on return on November 19th, and the contribution, as has been said, was eventually published in our issue of January 3rd, 1925. Subsequently we were informed that the patient had died, and on January 26th we received from M. Spahlinger the following letter, dated Geneva, January 12th:

"Sir,—With reference to the case of Mr. R. G. which appeared in one of your late issues, may I explain that this patient, who made such a rapid recovery, had started to resume normal life, when he contracted typical pneumonia, from which he died.—Yours faithfully, H. SPAHLINGER."

We have been independently informed by the Ministry of Pensions that their Medical Branch, from the particulars given in the article as published, recognized the case as one of which they had detailed information and that they had been officially notified on November 21st that "R. G." on October 25th, 1924, had a very copious hæmoptysis, and that from October 27th signs of pneumonia, with pneumococci in the sputum, developed and the case terminated fatally on November 3rd.

## ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

(Continued from page 230.)

### ADMINISTRATION AND PROCEDURE.

At the sitting of the Lunacy Commission on January 28th the examination was continued of Mr. Montgomery Parker, chairman of the National Society for Lunacy Reform. The principal discussion of the morning centred round the procedure on discharge of a patient.

The CHAIRMAN (the Right Hon. H. P. Macmillan, K.C.) said he had always felt that a difficult part of the Commission's investigation concerned the position of the authorities with regard to the recently recovered patient. The moment the patient was restored to sanity it was illegal to detain him, and yet, as in all illnesses, to fix the date of convalescence was difficult, and to restore the patient immediately to his old life would in many cases be detrimental. One solution would be to make the patient become, at the stage of recovery, a voluntary boarder, thereby taking him out of the category of legally detainable persons. Another suggested solution was the utilization of the parole system, but this would involve some infringement of the law, because a patient on parole was still subject to the legal nexus which should not apply to a sane person.

Earl Russell asked what the witness would do if he were a medical superintendent and had a case practically recovered—a case which if it came to him in its present condition he would not dream of certifying, but which he knew would suffer injury from being sent out immediately. Mr. Parker said that he would make such a patient a voluntary boarder. He recognized that before such patients were sent out on trial an investigation must be made as to their home conditions, and in the case of rate-aided patients the only practicable step might be to send them back to the infirmary.

The Chairman pointed out that removal from the care of the medical attendant who had achieved the cure to that of the Poor Law doctor who did not know the case at all, and into surroundings different and less suitable, would be a menace to the completion of recovery. Mr. Parker said that he would like the medical superintendent to tell the patient that he was free, but to add, "If you take my advice you will remain here another month."

Sir Humphry Rolleston remarked that the witness, in his desire to protect the individual from any lapse of efficiency on the part of the medical superintendent, urged the right of independent medical access. But from what source would the outside doctor get his information? Mr. Parker said that he would get it primarily from the patient, from the patient's friends, from other patients possibly, and from the case-book and other records. Sir H. Rolleston said that it seemed to him that the outside doctor would have to depend very largely on evidence furnished by the medical superintendent.

The Chairman remarked that in reading Dr. Lomax's book he had been impressed by the statement that in asylums the worst cases were those most insistent on release.

Some discussion took place on definitions, and the Chairman noted that in all the definitions which had been proposed to the Commission, including those brought forward by the British Medical Association,<sup>1</sup> persons were defined by the steps which it was necessary to take in dealing with them. They were defined by the consequences of their condition rather than by those attributes from which the consequences sprang. He felt that this must be so; a pathological definition would be impossible from the administrative point of view, and a workable definition must be based on conduct or ability.

A part of the evidence of the National Society for Lunacy Reform pressed for a more judicial character to be given to all proceedings prior to detention, the proceedings to be initiated by sworn information, and to involve the usual rights of cross-examination at the inquiry and the calling of rebutting evidence.

The Chairman here remarked that the British Medical Association, in Appendix A of its evidence, had collected, for a different purpose, the various sections of the Act in which the justice of the peace or the judicial authority was referred to as being clothed with judicial powers. The purpose of the Association was to emphasize the judicial character of the procedure and to plead that all persons taking part in the proceedings should enjoy protection, including, of course, the certifying doctor. The National Society for Lunacy Reform was looking at the matter, not from the point of view of professional safeguards, but from that of the rights of the patient. But if the society was laying stress upon the desirability that the proceedings should have a fully judicial character, with the doctors as witnesses, this, of course, would mean that the doctors must have the same protection as any other witnesses in a judicial proceeding.

<sup>1</sup> See SUPPLEMENT, BRITISH MEDICAL JOURNAL, January 17th, 1925, pp. 23-36.

Mr. Parker said that his society was against this demand on the part of the doctors. It seemed that the doctors wanted to pass on their responsibility, and to enjoy the immunity of witnesses in courts of law. His society did not suggest this. What was wanted from the doctor was a medical report for which he must be considered responsible.

The witness agreed, in answer to the Chairman, that there might be cases in which it would be inexpedient to disclose the medical opinion to the patient; if the judicial authority functioned efficiently the proposals of his society would be modified to that extent. He did not think that disclosures in regard to lunacy were any more serious than those in divorce, and residence in a mental hospital would become known generally, sooner or later.

Sir David Drummond questioned the witness as to whether he had any cases to bring forward in which it was alleged that patients were wrongly certified. Mr. Parker said that there were cases in which the mental disturbance was of only short duration, and such cases should not have been dealt with by way of certification. Sir David Drummond asked that the certificates in one such case might be put in, and the witness promised to comply.

Another contention of the witness was that when a patient was capable of making rational statements an inquiry into his case should be conducted publicly. Earl Russell asked whether it was really desired that, in addition to the relatives and other parties interested, the local reporter should be present, and serve up for the public all the medical and other details. The witness agreed that there were difficulties surrounding such a requirement, and finally he admitted that nothing was to be gained by publicity if the judicial authority could be relied on to function properly. He also said that few of the public, and not many practitioners, seemed to know what rights a patient possessed under the Lunacy Act. There should be a copy of the Act in the possession of every medical officer of health, and it would be a valuable step to have printed for popular use, on a card or in pamphlet form, the main provisions of the Act.

The Commission adjourned until February 9th.

## England and Wales.

### A DEPUTATION TO THE MINISTER OF HEALTH.

On January 27th Mr. Neville Chamberlain, M.P., the Minister of Health, received a deputation from the People's League of Health, who submitted to him a number of resolutions passed at the Conference convened by the League on the causes, treatment, and prevention of disease, held at the British Empire Exhibition last May.\* Viscount Burnham, in introducing the deputation, reminded Mr. Chamberlain that he had presided over the first section of the Conference and delivered an illuminating speech on the housing question, and said that the League existed for the propagation of health ideals and health knowledge and of health habits in the body politic. Sir W. Arbuthnot Lane submitted a resolution urging the appointment of an inter-departmental committee to prepare a pamphlet on proper food as the basis of health and the first step in the prevention of disease. Dr. Scurfield urged that the constitution of infant foods should be declared on the label, and asserted that preservatives were used as a substitute for cleanliness. Professor W. E. Dixon made the point that America forbade the presence of boracic acid in home-consumed foods, though there was no reason to suppose that foods exported to this country (which did not have any regulation preventing the use of boracic acid as a food preservative) did not contain boracic acid, which in an aggregate of small quantities was inimical to health. Sir Harry Baldwin declared that the surest way to strengthen the tissues against illness was by the general and generous consumption of wholesome in preference to devitalized white bread. Dr. Tredgold said that the many eminent mental specialists who were councillors of the League were concerned with the urgent necessity for provision of treatment for early cases of mental disorder; adequate treatment was also needed for children suffering from the after-effects of encephalitis lethargica. Mr. C. J. Bond, in dealing with the hospital problem, urged the department to institute contributions on insurance lines to a hospital service which should be co-ordinated in regard to methods, and particularly to method of discharge. Professor H. R. Kenwood

spoke of the evil effects of overcrowding, and stressed the point that tuberculosis infection was contracted chiefly in infancy. Professor S. Lylo Cummins, after paying a tribute to the tuberculosis work done by the Government, urged the co-operation of the Ministry and the Board of Education to remove children from crowded areas and place them free from infection in schools at the seaside or in the country. Dr. F. E. Fremantle, M.P., said that the consolidation of the Public Health Acts would make a composite machine for the formation of public opinion.

The Minister, in his reply, said that the Ministry had already issued a pamphlet on diet, and this was available for the public and for the League if they could make use of it; others would probably follow. But he doubted whether a Government department could properly undertake the issue of popular leaflets, which must necessarily be in a form open to criticism by specialists. Mr. Chamberlain then commented briefly upon the other resolutions put before him, expressing general sympathy with most of the aims thus declared. He said he proposed to accept generally the recommendations of the Food Preservatives Committee, which would be circulated in draft, so that the interests concerned could make out any case they had against them. With regard to smoke abatement, he had already given an assurance that a bill would be introduced, but with many Government measures urgently requiring to be passed through he doubted if it would be politic to introduce it this session. He reminded the deputation that when he had been in office before he himself introduced a bill for the early treatment of mental disorder; but the Government had gone out of office before this could pass through all its stages, and since then the Royal Commission had been appointed, which would necessarily delay any progress with the bill. But the fact that he had himself prepared the bill was an earnest of his intentions. On the subject of the mental and moral deterioration of children after encephalitis lethargica, he was informed that the Board of Education was about to make special provision for dealing with such children. With regard to hospital services, he assured the deputation that if what they were anxious to secure was better co-ordination, he was entirely at one with them. But the object aimed at seemed to him unattainable without the reform of the Poor Law. This the Government had undertaken to deal with, and intended to press it forward as quickly as possible. As to the risk of the spread of tuberculosis by infected adults, he quite recognized this, but thought it would be better to remove the source of infection from the children rather than the children from the source of infection. Many local authorities had in private bills taken power to remove tuberculous cases compulsorily, and he was prepared to give general powers to local authorities in amending the Public Health Bill which he contemplated introducing as early as possible. That bill would be a preliminary to the consolidation of the Public Health Acts, and he hoped it might be possible to get both those measures through in the coming session. He also hoped that, if not this session at any rate next, he would be able to get through a bill amending the Midwives Act on the lines suggested by the deputation.

### ALLEGATIONS OF ASYLUM ILL TREATMENT REFUTED.

A few days ago sensational paragraphs appeared in some of the daily newspapers, under startling headlines such as "Story of asylum inferno," and "Degrading asylum conditions," and said to have been made at a meeting of the Board of Guardians on January 22nd by some members of the board, following a visit to Hanwell Mental Hospital on January 6th. A member of the board was reported to have said that a courtyard in which patients were confined was like Dante's Inferno, and that fifty or sixty men were there huddled together in degrading conditions, half-clothed, with torn shirts, without coats or waistcoats, and with no shelter from the weather. With regard to these allegations the Mental Hospitals Committee of the London County Council informed the Council at its meeting on February 3rd that on January 6th seven members of the Wandsworth Board of Guardians, among whom was the member referred to, signed an entry in the visitors' book at Hanwell Mental

\* See BRITISH MEDICAL JOURNAL, June 7th, 1924, p. 1013; January 31st, 1925, p. 231.

Hospital in these terms: "We have this day visited the institution and the patients appeared quite as happy and comfortable as is possible!"

#### ROYAL UNITED HOSPITAL, BATH.

The annual meeting of the Royal United Hospital, Bath, was held on January 28th. The report of the management board for 1924 referred to the tragic death of Mr. Forbes Fraser, who was to have been President of the British Medical Association Annual Meeting this year. He had been the prime mover in the scheme for acquiring the site at Combe Park, and had lived to see part of the building plan completed—namely, the erection of the paying hospital for people of limited means, and of the orthopaedic hospital for crippled children. The Friendly Societies' Council in Bath had arranged during the year for the raising of an annual contribution to enable the receipts of the Royal United Hospital to balance the expenditure. The sum of £4,900 had been handed over, and so for the first time for very many years the board of management was able to produce a balance sheet showing a credit balance of £859 on the year's working. A further benefit derived from this scheme was that the general public were now taking a much greater interest in the work of the hospital, and large parties of visitors had been conducted round the wards. A notable event during the year was the official opening of the paying patient hospital, renamed the "Forbes Fraser Hospital," in May, by the Duke of Connaught, which was described in our issue of May 24th, 1924 (p. 915). The total ordinary income of the hospital during the year was £19,225, being an increase of £5,633 on the previous year. The total expenditure for the year was £17,319, as against £16,164 in 1923, and there was a debt of £7,000 to be extinguished. The total number of patients treated during the year was 8,156, as compared with 7,967 in the previous year; there was still a waiting list numbering 70. Sir Percy Stothert, chairman of the hospital, referred to the urgent need for transferring the work of the hospital to Combe Park, in order to do away with the waiting list and to provide better and more hygienic conditions for the patients. It had been decided to remodel the x-ray apparatus at the hospital at a total cost approaching £1,000. Mr. F. H. Pine, the chairman of the Friendly Societies' Council, referring to the part played by the friendly societies, said they were determined that the doors of the hospital should be kept open without the loss of a single bed. During the Annual Meeting of the British Medical Association next July there will be ample opportunity for members to see for themselves the great progress that is being made in the transformation of the Royal United Hospital.

### Ireland.

#### DECLINE OF TUBERCULOSIS IN CO. KILDARE.

Dr. J. BOYD BARRETT, medical inspector of the Department of Local Government and Public Health, reported recently to the Kildare County Council that there had been a satisfactory decrease in the occurrence of, and death rate from, tuberculosis during the last decade. Dr. Daly, the tuberculosis medical officer, attributed the decline to the improved conditions of life of the people; their better education as to the nature of the disease, resulting from propaganda and teaching at the tuberculosis dispensaries; the elimination of sources of infection by institutional treatment of patients; and the special treatment (including immunization) which the tuberculosis medical officer had given at the dispensaries to those who attended regularly. In 1906 the death rate per 1,000 population was 2.5; in 1909 2.3; in 1912 2.1; the average number of deaths was about 170 a year; in 1922 the rate was 1.45 and the number of deaths 89. There is still no central tuberculosis dispensary, but a centre for the distribution of propaganda, examination of sputum, examination of contact cases, and preservation of records is essential in every county. It should at the present time be considered in association with the provision of accommodation for advanced cases; and also with the recognition that most cases come from an

area south of Newbridge. The numbers under treatment have diminished. This is not due to the non-attendance of patients, but to the disappearance of the disease. A feature of the decline in attendance is that cures have been effected in many cases. There are instances of some families of whom the only surviving members are those who attended regularly for months, and even years, the tuberculosis dispensaries, and had undergone a special course of vaccine treatment. The local dispensary doctors have co-operated with the tuberculosis medical officer in many parts of the county. In Athy, Killeullen, Naas, Kilmeague, Kildare, and Newbridge they have agreed to visit tuberculosis patients, according to the requirements of the tuberculosis medical officer, and report on their condition. A fee of 5s. a visit has been accepted. Early pulmonary cases are treated at Peamount, where there are about twenty-five at present. Some selected patients who were isolated at home, and had a separate room, were treated locally. Such cases attend regularly at the dispensaries for tuberculosis treatment.

#### FERMANAGH COUNTY HOSPITAL.

At a recent meeting of the Fermanagh County Council the following letter was read from Sir Charles F. Falls, M.P., solicitor to the council:

"With reference to the scheme submitted to your council for the enlargement of the Fermanagh County Hospital, so as to make it capable of accommodating all the sick poor in the county, and to close the workhouse hospitals of Enniskillen and Lisnaskea, and to the questions you have submitted for my opinion, I have carefully considered the matter. I beg to state that, in my opinion, this council has no power to close the workhouse hospitals, but if you desire to adopt the scheme you can do so by entering into binding agreements, subject to the consent of the Ministry for Home Affairs, with the guardians of the two unions as owners of the hospitals, and with the two district councils as the sanitary authorities, that if and when the county hospital is made capable of accommodating and available for the use of all the sick and poor in the county they will close their workhouse hospitals and send their sick poor to the county hospital on such terms as may be arranged. It would appear to me that it would be necessary for the sanitary authorities to devote one of the hospitals as an asylum for infirm and chronic cases, and also to keep open one of the fever hospitals for the use of the whole county."

After a long discussion the matter was adjourned until it was known what was going to happen regarding the entire Poor Law and hospital system after the Commission has made its report. The scheme had been prepared by Dr. Kidd after considerable thought, and he did not think it should be turned down. Its consideration should be adjourned until the action the Government would take was known.

### Scotland.

SCOTTISH HOUSE OF THE BRITISH MEDICAL ASSOCIATION. ARRANGEMENTS have recently been made for the purchase by the British Medical Association of a Scottish house for the Association in Edinburgh. The building, which is situated at 6, Drumsheugh Gardens, will shortly be taken over by the Association, and was inspected last week by the members of the Scottish Committee. It consists of four floors and a basement with handsome interior fittings. On the ground floor is a room suitable for meetings of committees and a suite of rooms intended for the use of the Scottish Medical Secretary and staff. On the first floor a large room capable of seating about 150 people will be available for professional meetings. There is ample other accommodation for all the possible activities of the Association in Scotland.

#### PROTECTION AGAINST DIPHTHERIA.

A considerable amount of work has been done recently in Edinburgh in regard to the Schick test in relation to the protection of children against diphtheria. At a meeting of the Public Health Committee of the Town Council on January 20th Dr. W. Robertson, medical officer of health for the city, appealed to the authorities for assistance in a matter which he regarded as of vital importance to the health of the community. In a report he stated that almost a year had elapsed since the testing of school

children was begun in the Edinburgh and Leith area. In all twenty-six schools had been visited and a great amount of work had been accomplished, no fewer than 4,362 children having been tested. Of that number 3,362 had received inoculation. Not a single untoward result had come to knowledge as a result of the application of the test. Dr. Robertson expressed the opinion that the authorities ought now to proceed to secure protection for children of pre-school ages. In fact, the logical outcome of their experience was that efforts should be mainly concentrated on the protection of children before they began to attend school. Arrangements were now being made to deal with children of pre-school age at centres convenient for the attendance of parents, and it was hoped that parents would avail themselves of the opportunity to be present in order to protect children against a disease which so frequently endangered life.

#### EDINBURGH PARISH COUNCIL AND TREATMENT OF MENTAL CASES.

At a meeting of the Edinburgh Parish Council, held in the Council Chambers on January 19th, a discussion took place in regard to the policy to be adopted with reference to voluntary and observation mental cases. The chairman (Colonel A. Young) stated that until recently the lunacy law as regarded pauper cases had been entirely dependant upon certification, but there was a tendency to get away from that and to obtain power to give the benefits of treatment without certification of insanity. So far the movement was slow, and it should be the council's endeavour to accelerate the reform. He moved that the council should decide to accept voluntary patients if chargeable to the rates and pay the ordinary rate of board for them in a mental hospital, although this meant sacrificing the small grant which was obtainable on certification. The council agreed, and it was remitted to the chairman's committee to bring up a report in regard to the provision of accommodation for mental observation cases.

#### MEASLES AND WHOOPING-COUGH IN EDINBURGH.

An epidemic of measles of considerable extent and another of whooping-cough are in progress in Edinburgh. Since the notification of cases of these diseases was introduced at the outbreak of the epidemic the total numbers have been: measles 1,546, whooping-cough 481. At the meeting of the Edinburgh Public Health Committee on January 20th it was reported that since the last return a month ago the total number of cases of measles notified had been 525, of which 116 had been removed to hospital; the cases of whooping-cough notified numbered 208, and of these 35 were removed to hospital. The suburban districts of Liberton, Colinton, and Craigmoad had so far escaped the outbreak.

### NEEDS OF SCOTTISH HOSPITALS.

(Continued from page 23.)

The Committee appointed by the Scottish Board of Health to inquire into the inadequacy of the hospital services in Scotland resumed its sittings on January 27th at the offices of the Scottish Board of Health in Edinburgh, under the chairmanship of Lord MACKENZIE.

Sir HENRY KEITH, Provost of Hamilton, gave evidence upon a précis which he had prepared to the effect that, while hospital services were at present inadequate, this inadequacy would not be assistance should be given to public health authorities, and that into serious difficulty. With regard to remedying the present inadequacy, he thought the best way was to extend existing hospitals and to ensure co-operation between the existing hospitals and departments. He thought, further, that extension applied more to public health institutions than to general hospitals. This witness was strongly of opinion that venereal disease should be existing voluntary hospitals should be paid.

Dr. J. PANTARIS KISTOUR (Aberdeen) gave evidence with regard to the needs of Aberdeen Royal Infirmary, and said that there was urgent need in that city for new and more extensive institutional health services. The present was regarded as an opportune time for the provision of a common hospital site of such extent as to provide eventually for the whole hospital system of the city. He was in favour of the maintenance of the voluntary principle, but did not consider that it could provide adequate services in

Aberdeen. He believed that, if an adequate health service was to be maintained, greatly increased State grants must be made.

Mr. JAMES MAXTON, M.P. for Bridgeton, gave evidence regarding the Socialist view of Scottish hospital services. He said that for some time past the Labour movement had been giving the matter of hospital and health services very great consideration, and they had had advisory committees sitting for the last two or three years, of which the general finding was embodied in the pamphlet *The Labour Movement and the Hospital Crisis*.<sup>\*</sup> Organized workers, who wanted to play their part as citizens, found that they were called upon to pay a public health rate to the town council, poor rate, which included charges for certain health services, educational rate, national taxation, and generally in addition an organized weekly or monthly contribution in the work-shop. The workman also subscribed to hospitals through his trade union and through his co-operative society, and in addition was often called upon to take part in various sales, prize drawings, charity football matches, and other special entertainments, which all went to keep up a hospital system and general health services. In all, the witness believed that the working man subscribed to hospitals in perhaps ten different ways, and these contributions were paid with a reasonable amount of good will. It was, therefore, annoying that a waiting list should mean delay in admission, and a man felt that it would be better if, instead of paying in many different ways, he paid in one way—namely, through the rates. He also wanted to have the satisfaction of knowing that everyone who was engaged in a national or voluntary health service was a well paid worker, and there was a very widespread suspicion among working men that hospital staffs were overworked and not too well paid. There was no working trade unionist who wanted that. The view to which they came was that the nation should take complete responsibility for the organized health service, and they would bring about that change with the least disturbance possible of existing agencies. They would first expect the Board of Health in Scotland and the Ministry of Health in England to fill up the gaps; and they definitely took the view that the Poor Law institutions should be taken out of the hands of the parish councils and put under the control of the local health authorities. The witness said that they should place three options before voluntary hospitals: either that they should be taken over outright by the local health authority, or that they should remain absolutely outwith it as they were to-day, or, thirdly, that they should receive grants. He thought that the best feature of the voluntary hospitals was the fact that they had been recognized as centres where the finest equipment and the most skilful physicians could be obtained, and they did not want anything inferior under a public service. The average working man, usually a fairly healthy citizen, would be prepared to pay the extra cost in return for the knowledge that hospitals were being run in a business-like fashion, but at present he felt that the methods of getting funds were cumbrous, involved, and irritating.

Mr. JOSEPH F. DUGAN, general secretary of the Scottish Farm Servants' Union, giving evidence, alleged that various forms of social pressure were employed to secure income for hospitals from the community, and he thought that a more economical method of providing money would be by taxation or rating. He thought, at the same time, that a certain amount of the expenditure ought to be borne by national funds, because hospital service was really more a national purpose than a regional one in some areas. He did not regard a regular levy on wages, which had been extensively adopted, as any more a voluntary contribution than the ratepayer's contribution to local authorities. He contended that the present system was wasteful in the extreme and unequal and unfair in its incidence. The first necessity, he thought, was a single local health authority.

Mr. JOSEPH SULLIVAN, former Socialist M.P. for North Lanark, next gave evidence. He considered that the hospital facilities were inadequate, especially in populous areas, but he thought that some of the money at present wasted on hospitals might be better expended on improving housing conditions. This witness criticized the work of voluntary hospitals, and expressed the general view that the work in them would be more satisfactory if the staffs were paid.

Mr. DAVID BERTHAUD, of the Ancient Order of Foresters, Broxburn, agreed that any compulsory method would be bound prejudicially to affect voluntary income, but he had no complaint to make against existing hospitals, except as regards accommodation. He said that in his area 2d. a week was deducted from every workman's wages by the employer on behalf of the Royal Infirmary of Edinburgh. The large waiting lists of hospitals were bound occasionally to extend periods for which sickness benefit was claimed from approved societies, although the greater number of persons on the waiting lists were able to continue in their employment whilst awaiting admission. He believed voluntarism to be an ideal in hospital working, but when accommodation was inadequate in every voluntary hospital other sources of revenue must be considered, and he preferred national insurance help.

Professor L. TUNNON PRICE, professor of surgery in Dundee, giving evidence, said that at Dundee Royal Infirmary there were 436 beds, and it was estimated that the additional number required would be 126. The inadequacy could be largely, though not entirely, measured by the waiting list. He thought that any additional provision that might be required should, however, be met by an increase in hospitals of the convalescent type. In Dundee, for example, there was a convalescent home containing 65 beds, which was not sufficient for a town of that size. This witness thought that independent management of hospitals was vital, and was probably the most efficient form of management that could be devised, as the average individual associated with the voluntary hospital in the capacity of director very soon became interested and enthusiastic and sacrificed a good deal of his time

<sup>\*</sup> See BRITISH MEDICAL JOURNAL, April 8th, 1922, pp. 570-3.

for the maintenance of a high standard. He thought that if times improved the voluntary effort would improve, especially if it were augmented by a grant from the State towards building, which had swallowed up a good deal of the capital of hospitals in the past. He was of opinion, however, that if the State, in giving grants, made a condition that it should interfere with the management of a voluntary hospital, they would do better to refuse the grant.

Dr. JOHN M. JOHNSTON, medical superintendent of Stobhill Hospital, Glasgow, together with Mr. M. A. REYNARD, clerk to the Parish Council and District Board of Control, Glasgow, gave evidence on a précis which they had drawn up. The Poor Law hospitals in Glasgow, it was stated, served the purpose of auxiliary hospitals, and little difference could be drawn between the patients entering them and those entering the general hospitals. Every resident within the parish had the right to demand admittance, and there was no waiting list for the Glasgow Poor Law hospitals. At the present moment, indeed, there were vacant beds for about 400 patients. It was very largely a fallacy to say that treatment in a Poor Law institution had a pauperizing influence on the individual. Many of the patients who applied to them for admission were in possession of small incomes, ranging from 10s. to 30s. a week, or had relatives who were legally and financially able to support them. In cases of this kind part or the whole of their maintenance was recovered, and the charge to the rates was thus lightened. Alluding to the suggested co-operation between voluntary and Poor Law hospitals, these witnesses said that this would be welcomed by the Poor Law authorities in Glasgow. It would be an excellent plan to take over a portion at least of the waiting lists at the general hospitals. There were, however, obstacles to this, especially in the stigma of pauperism which applied to the treatment of disease under the Poor Law. This was an anachronism, and if the Government were to amend the Poor Law Act, the Poor Law hospitals (in Glasgow at least) could give valuable assistance to the voluntary hospitals without restriction or reserve.

## Correspondence.

### ELECTRONIC REACTIONS OF ABRAMS.

SIR,—Feeling interested from a psychological and ethical point of view in the so-called electronic reactions, I submitted Sir Thomas Horder's report to a friend, who is an accomplished physicist and electrician, and I am sending you the notes with which he has supplied me. They are, I think, deserving of serious consideration at a moment when we seem to be threatened with a new and mischievous outbreak of credulity and suggestibility.—I am, etc.,

London, S.W., Feb. 3rd.

JAMES CRICHTON-BROWNE.

#### Enclosure.

I duly received your letter and copy of the BRITISH MEDICAL JOURNAL with the address of Sir Thomas Horder on the Abrams electronic reactions. I have carefully read the address, and I agree with your opinion that it cannot be regarded as a satisfactory treatment of the subject. Having regard to the copious use of this method and the condemnation which has been pronounced upon it by the *Scientific American* committee and others, I think we had the right to expect from Sir Thomas Horder and his colleagues a much more lucid and critical exposition of the whole affair.

The report seems to me defective in not giving a more thorough analysis of the method and explaining what it is and what it is not. The committee has not been able apparently to strip off the garment of mystery or deliberate mystification in which it was clothed by Abrams and redressed by Boyd.

There is no attempt to separate out carefully the physical, physiological, and psychical factors in the affair. Abrams was a great coiner of new and fantastic words, and called familiar pieces of apparatus, such as resistance coils, condensers, etc., by cunningly chosen words so as to suggest they possessed powers which they have not been proved to possess, and these absurd terms have been retained.

Looking at the sketch of Abrams's apparatus given by Sir Thomas Horder I find in it: (1) an earth connexion on the left hand; then (2) some kind of support for holding the blotting paper specimen called a *dynamiser*; then (3) a variable resistance coil called an *amplifier*, but it amplifies nothing; (4) two step-by-step resistance coils called *reflexophones*; (5) a boy or subject, who has an electrode on his forehead and his feet apparently on an earth-plate. In other words, there is a living subject with his head and feet connected through variable resistances and the specimen. The committee has given us no measurements of these resistances in ohms, nor any idea of the magnitude of the electromotive forces or currents which must be set up by thermo-electric action at the junctions, or electro-chemical action due to moist skin, etc., or muscular electric currents. The boy apparently acts as a sort of "detector," like the crystal in a wireless set. The operator taps his abdomen, and by the variation of the sound is supposed to be able to pronounce on the nature of the specimen.

The committee does not tell us what these sounds are or whether they are easily recognized, like stethoscopic sounds of heart beat, breathing, etc. They do not seem to have varied the boy or ascertained whether the boy's state of health or repletion as regards food, etc., made any difference, and whether the same results were obtained with the same specimen but a different boy and different operator. There seem to have been no proper control experiments. I do not agree with Sir Thomas Horder's method of estimating by the law of probabilities the chance of error. To make this method valid a very large number of observations are necessary. Broadly and generally speaking, I do not think that the investigation was conducted on such lines as to separate out the different factors or to definitely exclude certain causes of error or deception. Unless an effect or phenomenon can be repeated or observed in such fashion as to exclude the personal, incommunicable element in it, it cannot be the subject of scientific investigation properly so called.

Even in spite of the general denunciation of the Abrams method which occurs at the end of the report, I think it is to be regretted that there is in it a disposition to regard the method as having "something" in it. Such an opinion coming from Sir Thomas Horder, however cautiously expressed, is sure to give encouragement to the charlatan and quack.

The report does not help us in the least to decide whether there is any new physical effect involved, such as was the case with the x rays and radium, or new therapeutic agency as in the case of ultra-violet light.

It leaves the whole thing surrounded still with unintelligibility, and no illuminating ray has been shed on it from the dry light of accepted scientific knowledge. I hope I am not wrong in this opinion, or have done any injustice to an investigation which evidently took a long time, involved much expense, and showed a strong desire on the part of the eminent investigators to get at the truth.

SIR,—May I venture to submit to you my reasons for thinking that the discussion of "E.R.A." in your columns will be barren of results? There are now three parties in the contest: critics such as Professor A. J. Clark, who, though anxious to investigate, are hindered by mysterious restrictions from doing so; Sir Thomas Horder's committee, which has been content to accept the restrictions, and has recorded its views on observations of the action of a variant of the Magic Box; and actual priests of the cult, the woolliness of whose mental state, however much they may vary in technique, is sufficiently indicated by Dr. Oscar Parkes's letter. Outside the arena is a stolid mass of indifferent medical practitioners; also some enthusiastic members of the lay public who think that they have been cured of obscure and intractable diseases by means of "E.R.A." The same position has arisen in sundry other "stunts" throughout the ages; in a few, such as mesmerism, a scientific discovery has been made; others, such as phrenology, have been represented by a process of distortion as the precursors of a branch of science; while the majority, such as spiritualism and sour milk, have been, or probably will be, committed to the limbo of things forgotten.

With Professor Clark's attitude no fault can be found. He has tried to get an impartial investigation of an alleged method of diagnosis and treatment. He is offered just as little scope as falls to the lot of the inquirer into the doings of a medium within a black-curtained cabinet. Therefore his admirable letters are wasted. Sir Thomas Horder's committee, on the other hand, has to bear a heavy weight of responsibility. The committee set out to investigate a mechanical method; it was met by a refusal to allow proper scientific investigation; it could only record its observation of results much as a member of the audience at Maskelyne and Cooke's might do; and the committee solemnly records that there is "something in it." So there is in ectoplasmic emanations at one of Sir Conan Doyle's seances—something, probably, very solid and materialistic. I cannot help thinking that the investigations of Sir Thomas Horder's committee are really worse than useless; they degrade the standard of scientific observation because they were undertaken with the imposition of conditions which no scientific observer should accept. It is all too like the pitting of the wits of a conjurer against those of his audience.

Electronic practitioners present the problem that always arises with any new cult which lends itself to remunerative enterprise. Probably in most cases there is no reason to

doubt the sincerity of the spiritualist, the crystal gazer, the man who sees auras round his patients, or the practitioner who treats all disease with the outward application of paraffin oil. The human mind is capable of persuading itself of many things. But it is just this capacity which should make medical men very chary of taking up the practice for gain of an unusual nostrum unless and until full opportunity for investigation has been given. The Society of Electronic Medicine may pour forth pages of such letters as that signed by Dr. Oscar Parkes, but the letters are valueless until the whole procedure and mechanism in "E.R.A." becomes open and above-board.

To widen the scope of my criticism to its utmost capacity a word may be said on the stolidness of the mass of the medical profession. Sir Thomas Horder has the credit of not disdaining to look into a treatment because it is new. But the majority of us are disinclined to show interest in any suggestion that is outside our usual routine. This seems to me to be a mistake; medical men, who have all been trained in science, should be willing to investigate scientifically any new suggestion, even if the only result is to elucidate the psychology of the suggester. But restricted investigations such as those of Sir Thomas Horder's committee might very well be kept out of the public press.—I am, etc.,

Felstead, Essex, Feb. 2nd.

CHAS. BUTTAR.

#### NOTIFICATION OF PULMONARY TUBERCULOSIS.

SIR,—The conditions with regard to the notification and treatment of pulmonary tuberculosis appear at present to be far from satisfactory. The notification of this disease, instead of being advantageous to the patient and tending to reduce its incidence, has the opposite effect. So severe are the stigmata attached to the unhappy sufferer, so great and so many are the inconveniences resulting from notification, that many practitioners, from motives of self-protection, are loath to notify until the disease can no longer be concealed from laymen, and even in cases of death from tuberculosis refrain from entering such as the cause of death where evasion is possible. This latter practice is probably a potent agent in the apparent fall of the death rate in tuberculosis, and gives rise to an unfounded optimism in those who compile and study statistics.

Should a patient, at present, seek admission to a public sanatorium, he is subjected to an ordeal from which the guilty possessor of a positive Wassermann reaction is carefully shielded. The word "sanatorium," in itself, has come to bear an unfortunate connotation and could be more euphemistically and more advantageously referred to as a "home for treatment of respiratory diseases," or some such non-committal name, thus relieving early cases amenable for treatment from the difficulty of choosing between robust health and idleness and continued employment with intermittent invalidism, often terminating in premature death. Such cases, unfortunately, must be branded before admission, and, though this is done ostensibly in the interests of public health, no department is prepared to give indemnification for inconvenience and (too often) for financial loss both to patient and relatives. Just as there would be more reason in closing sanatorium windows and opening all others, than in indiscriminately advocating "fresh air" in sanatoriums while most of the outside populace live in a self-imposed fetor, so would it be more sensible to notify those who become a source of danger from refusing to undergo treatment, and to leave unnotified those who are prepared to undergo treatment and so become non-infectious or at least versed in the art of prevention.

By the name "sanatorium" and all that it implies, patients are hindered from receiving early treatment through reluctance to seek admission. By the system of notification and its attendant stigmata, early diagnosis is prevented, dangerous concealment is fostered, the date of seeking medical advice is postponed, and thus the medical officers of the various sanatoriums are prevented from treating those cases which alone can receive benefit.

In view of the manner in which notification entails social stigmata, loss of employment, probably false statistics, certainly great inconvenience to patients and relatives—

even to exclusion from certain State services, not only of themselves, but of their children—it is not surprising that the sanatorium medical officer is prevented from realizing his proper function and that the apparent incidence of tuberculosis is rapidly declining.—I am, etc.,

WILLIAM G. WATSON.

Ayrshire Sanatorium, Glenafton,  
New Cumnock, Jan. 24th.

#### THE DIAGNOSIS OF ACUTE DRUNKENNESS.

SIR,—I welcome the criticisms of Sir Charles Ballance and Dr. Maurice Cassidy, the chief surgeon and chief physician respectively to the Metropolitan Police, on the subject of my modest address on drunkenness.

I am gratified that it afforded them "interest and amusement." But it is evident that their interest must have flagged before they reached the end of my address, otherwise they would have noted that, so far from degrading the skill or independence of the medical officers of police, I specifically stated my firm belief that, in cases where there seemed any uncertainty as to a prisoner's sobriety, the medical officer ought to, and as a matter of fact generally does, give the prisoner the benefit of the doubt.

Sir Charles and his colleague are disappointed that my address had so little to offer in the way of new signs or symptoms of drunkenness, apart from a suggestion as to examination of the cerebro-spinal fluid. I must indeed have failed in my exposition when I tried to point out that the so-called signs of alcoholic disability of the central nervous system, whether cerebral, cerebellar, ponto-bulbar, or otherwise, can each of them, individually, be produced by many causes other than alcoholic intoxication. This craving for a new sign implies a total misapprehension of the lesson I wished to convey. St. Paul remarked to the Corinthians that "the Jews require a sign, and the Greeks seek after wisdom." I should have expected Sir Charles and Dr. Cassidy, on this occasion at any rate, to be amongst the Greeks.

It is still more surprising to find that my distinguished critics range themselves alongside the medical officer who, at the discussion which followed my address, vigorously expressed his view that it was "a grave responsibility to differ from the opinion of a police surgeon." I agree. But it may at times be our duty to take that responsibility, rather than assent to a sober man being unjustly convicted of drunkenness.

If all police surgeons actually conformed to the standard of clinical examination carried out by Sir Charles and Dr. Cassidy the percentage of errors, small as it is, would be still lower. Some police surgeons tell me that in a doubtful case they habitually spend half an hour or longer in their clinical examination of the prisoner. These are medical officers from whom one would be very chary in differing. But there are others. I personally know of cases where a perfunctory examination of a few seconds is all that the prisoner gets. The police surgeon smells the man's breath, tells him to walk along a straight line and back, looks at his pupils (!), and then says, "You are drunk." No doubt in nine cases out of ten, in spite of this crude examination, he happens to be right. But I cannot but be sorry for any sober citizen who may happen to fall into the hands of such a medical officer, if he meets him "professionally" at a police station after dinner.

My statement that medical officers differ widely in their susceptibility to suggestion on the part of police constables is so conspicuously accurate as to be almost a truism. So long as medical officers are human beings, so long will they share this human characteristic. In youth, my Presbyterian upbringing prevented me from accepting the dogma of papal infallibility, and now, at my time of life, I am not likely to subscribe to this new dogma of the infallibility of police medical officers, good as they are. And so I stick to my guns, inwardly comforted by the solace of feeling that Sir Charles Ballance and Dr. Cassidy are really in agreement with me after all.—I am, etc.,

London, S.W.1, Feb. 2nd.

J. PURVES-STEWART.

P.S.—I have also much enjoyed their jocund reminiscences of the hump supper.

## WOMEN DOCTORS.

SIR,—An analysis of the further careers of the women graduates in medicine of the University of Bristol shows the following:

Of 20 women who have obtained their degrees during the past ten years, 14 have held resident appointments in the hospitals in which they were students, and some of them have held more than one appointment; 3 married immediately after graduation. One of the remaining three has obtained a resident appointment in a hospital outside Bristol.

Besides these there are several others—that is, those holding degrees from other universities or licences to practise—who have held resident appointments in Bristol. The proportion of those who have held resident posts is higher among the women than among the men in comparison to the number of the students of each sex. I may also mention that two of the senior assistants to the full-time medical professors in the University are women.

This does not appear to indicate that there is any prejudice in this school against women as such.—I am, etc.,

WALTER C. SWAYNE, M.D., B.S.

Clifton, Bristol, Jan. 27th.

SIR,—Dr. Mabel Ramsay (January 24th, p. 192) accuses the hospitals of prejudice against women, but let us examine the question a little more carefully.

Let us accept, for the sake of argument, her statement that the ratio of newly qualified women to men is about one to five; but what is the ratio of women to men amongst those entering general practice? Is it one to fifty?

Now the base on which the hospital rests is the general practitioner. He it is who makes the primary selection and who sends up the majority of cases for further diagnosis and treatment. It is upon his discrimination that the clinical material which reaches the hospital mainly depends. Do the abdominal catastrophes reach the hospital in a favourable or semi-dying condition? Have the cases of rheumatic endocarditis or empyema been detected and sent up in an early stage? These and a hundred other things of importance to the good work of the hospital depend on the training of the general practitioner.

It is true that wide professional training for a public official such as a school medical officer is of advantage to the community, but neither is the necessity so urgent nor is the hospital training so directly of value as in the case of the general practitioner.

The case is not one of sex. If all men were obliged to choose their career immediately upon qualification, there is little doubt, I think, that the resident hospital posts would be given by preference, and rightly so, to those whose choice was private practice as against public services.

When women as a body have shown themselves capable of shouldering the responsibilities and worries of practice it will not be long before they are admitted as readily as men to hospital posts.

I am acquainted with hospitals which have taken considerable pains to surmount difficulties of accommodation and professional organization in admitting women residents, only to be rewarded by seeing their late female staff drifting into semi-employed routine official work.

If public opinion, as Dr. Ramsay says, is on the side of the woman doctor, why has the latter failed to reap the golden harvest of private work which the demand for her services implies?—I am, etc.,

Sheffield, Jan. 27th.

A. E. NASH.

SIR,—Dr. Frances Braid's judicial letter in the JOURNAL of January 31st (p. 239) was refreshing to read after the special pleading in some of the previous communications on this subject in your columns. We all, I think, admit that there is a definite place for medical women in this country and that we have come to stay. On the other hand, there does not seem to be an urgent public call for increase in our numbers, and I think that it is this regrettable apathy on the part of the general public rather than professional jealousy of male colleagues that is the real cause of the absence of women on the honorary staffs of our large hospitals.

With regard to the question as to whether children should be treated by women rather than men doctors, it is to be remembered that children are comprised of both sexes, and it is quite conceivable that a little boy (and even, perhaps, a little girl!) might prefer to be treated when ill by a "gentleman doctor." Our most eminent paediatricians continue to be men, and the most successful are those whose personal qualities endear them to their little patients. With regard to women patients, there will always be those who prefer to be treated by doctors of their own sex, just as there will be those who, *ceteris paribus*, prefer a male doctor.

Before August, 1914, there was no apparent glut of women doctors, and those who were competent could always be assured of employment. When the war came there was a large increased temporary demand for doctors as such—not women doctors. Unfortunately it was then the short-sighted policy of those in authority to encourage young women, suitable or otherwise, to flock to the medical schools. The result of this is the unfortunate state of affairs which we see to-day.—I am, etc.,

London, W.1, Feb. 2nd.

EVA McCALL, M.D., D.P.H.

## FREUDIAN DOCTRINE.

SIR,—I cannot help thinking that Dr. William Brown's letter in your issue of January 31st (p. 239) accepts a principle which, if allowed to pass unriticized, and more particularly if generally acted upon, would do untold harm. May I venture to emphasize my point by an analogy?

There is a form of deafness the pathology of which was not understood at the end of last century, and which is even now not completely understood. It was then described as progressive middle-ear deafness, and, being difficult to treat, gave rise to the promulgation of various fanciful theories as to its being due to defective action of the muscles of the middle ear and palate. Faulty innervation of these muscles was said by some to be the cause, and treatment on the lines so suggested was stated to have been successful, but experience failed to justify this claim. Now it is true that in some of these cases the patients hear rather better when they are feeling bright and well, while depression and fatigue make them temporarily worse.

Let us suppose, then, that an otologist had propounded the view that this form of deafness was due to a lax condition of the "psyche" and that by suitably stimulating it good results could be obtained, and that the said otologist had a small following of believers in his method. Let us assume, further, that this method entailed much expenditure of time and, in the case of private patients, also of money. Let the originator of the treatment and his small following take up the position that it can only be criticized or even discussed by those who have practised it, or, better still, by those who have had their "psyche" stimulated.

In view of such a position as I have sketched would Dr. Brown recommend patients to give the treatment a trial at once, with all its expenditure of time and money, or would he prefer to "wait and see" how it appeared after discussion and criticism by otologists and neurologists generally?—I am, etc.,

York, Jan. 31st.

P. McBRIDE.

SIR,—I gather from the replies to the question I asked, with your kind permission, in the JOURNAL of December 20th, 1924, concerning the desirability or otherwise of the formation of some weighty conference on the basic doctrine and the practice of the modern school of "psycho-analysis" (commonly called Freudian), that my suggestion has met with but little encouragement from such of your readers as may either dissent strongly from this doctrine or regard it with indifference. On the other hand, it appears that those adherents to Freudism who have sent replies to my letter, when making their comments and suggesting certain conditions, have not sufficiently considered what kind of discussion I thought of as desirable.

I suggested an open discussion of similar weight and

authority to the recent conference of the Institut des Hautes Etudes in Belgium; and also gave my reasons for saying that no such gathering has as yet taken place in this country. Dr. Charles Harford, in his letter to you of January 31st, has proposed a measure which would exactly meet my views. Hitherto, however, my efforts have not succeeded in securing any due consideration of this subject, anywhere, within any nearly definite date.

I have just re-read all the letters which have recently appeared in your columns about this question, but am unable to regard any of the "discussions" and "criticisms" which Dr. E. Jones mentions (I have seen most of them) as coming at all within the scope of such a conference as I deem needed. Dr. William Brown's dictum that no proper discussion of "psycho-analysis" can be carried on by those who have neither practised it nor submitted to "analysis" themselves precludes, of course, all discussion with those who are not convinced psycho-analysts. But this is not Dr. Brown's opinion alone; it is insisted on by, I believe, all or nearly all psycho-analysts (not psychotherapists).

Through your courtesy I have had at least some intelligible reply to my query; and I trust I have not exceeded my undertaking not to discuss psycho-analysis afresh.—I am, etc.,

London, S.W.1, Feb. 3rd.

BRYAN DONKIN.

### GOLD TREATMENT OF TUBERCULOSIS.

SIR,—In view of the recent articles in the *BRITISH MEDICAL JOURNAL*—on November 8th and 22nd, 1924, and again on January 24th, 1925—relating to the gold treatment of tuberculosis attributed to Professor Holger Moelgaard, I write to call attention to a preliminary note by me which appeared in the *Medical Quarterly of the Soldier's Civil Re-establishment of Canada* for October, 1919. In this I pointed out that Koch had found that the cyanide of gold compounds possessed a surpassing activity in retarding the development of the tubercle bacillus, and that in the use of the double cyanide of gold and potassium for the treatment of tuberculosis I was disappointed to find that no specific influence was exerted on the course of the disease.

The advent of the colloidal preparations of the metals completely changed the outlook. After further prolonged investigation, a double colloidal cyanide of gold and potassium was prepared. To this compound, for the sake of brevity, the name "auro-cyanase" was given; it has since been obtainable from any chemist of repute. Treatment with this was found to be effective in all stages of tuberculosis, relieving much of the distress even in the very late stages.

Administration intravenously, in the initial stages of treatment, was found inadvisable as there was produced a temporary paralysis of the leucocyte-forming tissues, an effect most undesirable. Subcutaneous injection over the deltoid was substituted. Even with this method certain transient unfavourable features developed—for example, a general reaction varying in intensity with the stage of the disease. This was regarded as being in large part due to the liberation of endotoxins from the bacilli. Bearing in mind the claim of Besredka that leucocytic extract neutralized the endotoxin of tubercle bacilli, this was administered simultaneously with the injection of auro-cyanase. This measure was found effective in preventing the general reaction. It was later found to be an added advantage to give the leucocytic extract before and after the auro-cyanase.

In view of the above statements, I feel entitled to the claim of being the originator of the colloidal gold treatment of tuberculosis. In my note in the *Medical Quarterly* I gave a very brief summary of the result of treatment in several cases; stress of work at that time prevented a more detailed account. I hope shortly to report my experience since the appearance of my original article. In so doing, full details of the technique, dosage, and precautions to be observed during treatment will be given.—I am, etc.,

London, Jan. 28th.

A. COWAN GUTHRIE, M.B. Edin.

### SHAVING THE VULVA.

SIR,—With reference to the letter of Dr. Henry Corby (January 31st, p. 235), in which he condemns the fashion of shaving the vulva during labour—I presume he means before labour commences—I agree with him that this process is unnecessary and that it is repulsive to most women.

I pointed this out in a paper entitled "The sterilization of the skin of operation areas," published in the *BRITISH MEDICAL JOURNAL* of August 14th, 1909. This paper describes the method, originated by me, of sterilizing the skin with tincture of iodine. In a further contribution on the same subject, published in the *BRITISH MEDICAL JOURNAL* of June 4th, 1910, I emphasized the point that the repulsive process of shaving is unnecessary. Since adopting the method of sterilization with tincture of iodine I do not allow the pudenda to be shaved prior to operation on the abdomen. All that is necessary is that the tincture of iodine should be thoroughly rubbed in. I have always found this effective.

A normal confinement is quite disagreeable enough without adding unnecessary discomfort. Such a process as shaving the vulva encourages the present-day tendency to evade motherhood; whereas we should do all in our power to encourage motherhood.—I am, etc.,

Kidderminster, Feb. 2nd.

J. LIONEL STRETTON.

### WET WINDS AND EARLY PHTHISIS.

SIR,—I am sorry to have to draw attention to two serious misstatements in Dr. Ward's second letter.

1. *The South Devon Cases.*—The facts are as follows: Having received from Dr. Ward, not the statistics which we had all agreed on, but figures of much less value. I sent him a map of South Devon and asked him to kindly have the sites of the patients' houses marked on it and to indicate the patients' fates. This map came back so curiously marked that I could not credit the markings—for instance, the three cases of arrest in Dartmouth were marked as living in full exposure on the top of the hill; on inquiry I found that they really lived in the sheltered part of the town. So I took a fresh map down to Torquay and asked Dr. Ward to show me where to mark the sites and to say which he considered sheltered and which exposed. This he did quite willingly. In only five cases did he leave me to decide doubtful exposures; these I marked in a special way, as was only fair to us both, to distinguish them, and told Dr. Adkins that I had done so. I have all these documents. I by no means agreed with all Dr. Ward's assessments. Therefore when Dr. Ward writes that "Dr. Gordon was inclined to make me co-responsible for the result, but I was unwilling," he displays a singular forgetfulness. What has apparently annoyed Dr. Ward is that, on the whole, his own figures bear out my contention. But why be annoyed?

2. *The Work of Dr. Adkins and Dr. Datt.*—This interesting work has been carried out in quite a different way from mine. Only the actual house of the patient has been assessed as to its exposure or shelter by local examination. But it cannot be too clearly realized that that is by no means the same thing as I have done. All my work has been done by assessment from the map, of what may be called the personal exposure or shelter of the patient himself in the locality in which he lives. I thought that I had made that clear. My work on Exeter streets was partly undertaken to show that the effect of the winds was on the patients rather than on the houses, because it had been suggested that the winds acted by driving wet into the walls. Obviously differences between the results of two so different modes of inquiry do not necessarily show inaccuracy in either. Dr. Ward has not stated, as he should have done, that a different method had been used.

Again, the figures which Dr. Ward mistakenly supposes to have been thus shown erroneous are not solely "Dr. Gordon's," except in the five cases already mentioned, in one of which the wrong assessment is due simply to Dr. Ward having indicated the site wrongly. Many of these figures are Dr. Ward's own. To write, therefore, that "other

observers . . . investigating independently Dr. Gordon's decisions about shelter or exposure, but with no knowledge of the patients' fate, differed from him in 58 per cent. of 113 cases" is a serious inaccuracy. I shall check his figures presently.

I cannot imagine what Dr. Ward thinks that he effects by these letters. Does he desire to stimulate inquiry, or to stifle it? In any case nothing can be gained by misstatement.—I am, etc.,

Exeter, Jan. 30th.

W. GORDON.

### THE INFECTIVITY OF SMALL-POX IN THE INCUBATION STAGE.

SIR,—The view that small-pox is infectious in the incubation period, to which your reviewer takes exception in his very kind appreciation of my book on *Acute Infectious Diseases* (JOURNAL, January 24th, p. 166), is one that is held by several well known authorities, as is shown by the following quotations from recent literature:

"Il convient toutefois à remarquer qu'une variole peut être contractée auprès d'un malade en incubation de la maladie." [It should be noted that small-pox may be contracted from a patient incubating the disease.] (P. J. Teissier, *Nouveau Traité de Méd.* (Rogier, Vidal, Teissier), 1922, ii, 240.)

"Es liegen einwandfreie Beobachtungen vor, wo sich schon das Inkubationsstadium, sowie das Initialstadium als infektiös erwiesen." [There are undoubted cases in which the incubation stage as well as the initial stage have proved infectious.] (*Jochmanns Lehrbuch der Infektionskrankheiten*, second edition, 1924, 853.)

"Der Pockenranke ist in allen Stadien der Krankheit für Gesunde als infektiös zu betrachten, sogar in Inkubationsstadium wesshalb bei ihm noch keine Krankheits-symptome wahrgenommen werden, sind Übertragungen von ihm auf Gesunde beobachtet worden." (Schäper.) [The small-pox patient is to be regarded as infectious in all stages of the disease; even in the incubation stage when no symptoms have been noted cases of transmission from the sick to the healthy have been observed.] (F. Röhl, *Handbuch der inneren Medizin* (Mohr u. Stähelin), second edition, I Bd., I Teil, 1925, 120.)

—I am, etc.,

London, S.W., Jan. 24th.

J. D. ROLLESTON.

SIR,—May I emphasize the importance of the point raised in your review of Dr. J. D. Rolleston's *Manual of Acute Infectious Diseases*? In my experience of thirty-nine years in dealing with 1,200 cases I have had no reason whatever to credit small-pox with any infectivity during the incubation stage, with the possible exception of "bed contacts." Preventive measures based on this assumption have been consistently successful.—I am, etc.,

Bristol, Jan. 27th.

D. S. DAVIES.

### PNEUMOCOCCAL PERITONITIS.

SIR,—I should like to make one or two corrections in your account (January 31st, p. 215) of my remarks at the discussion on pneumococcal peritonitis at the Royal Society of Medicine on January 23rd. You say that "only 15 cases had been diagnosed since 1918, and only 7 of these had grown pneumococcus from the exudate. Of the 15 cases diagnosed as pneumococcal peritonitis, 5 recovered and 10 died." Unfortunately, the lantern slide giving the details of the cases which I took with me to the meeting was found unsuitable for use with the lantern, so that I had briefly to refer to the details of the cases, and no doubt the errors arose from my giving these details rather hurriedly. My actual words were as follows:

"I have gone through the records of acute peritonitis for the past nine years (1916-1924) and, excluding cases of tubercular peritonitis and septic peritonitis, following appendicitis, I have found no more than 15 cases in all, less than half being of pneumococcal origin."

Of the 15 cases of peritonitis due to various organisms, 5 recovered and 10 died; but of the 7 cases of pneumococcal peritonitis 6 died and only 1 recovered.

This shows that, so far as the Great Ormond Street Hospital is concerned, cases of pneumococcal peritonitis are even rarer than the report of my remarks would make them appear to be.—I am, etc.,

London, W.1, Feb. 2nd.

DAVID NABARRO.

## Medico-Legal.

REX v. BATEMAN.

APPLICATION FOR LEAVE TO APPEAL GRANTED BY COURT OF CRIMINAL APPEAL.

AN application on behalf of Dr. Percy Bateman, of New Cross Road, London, was heard in the Court of Criminal Appeal, before the Lord Chief Justice of England, Mr. Justice Salter, and Mr. Justice Fraser, on Monday, February 2nd. The application was for leave to appeal against Dr. Bateman's conviction for manslaughter at the Central Criminal Court in December last (see BRITISH MEDICAL JOURNAL, December 20th, 1924, p. 1179), when he was sentenced by Mr. Justice Shearman to six months' imprisonment in the second division. The application was threefold: (1) an application for the prisoner to be present at the hearing; (2) an appeal from an order of Mr. Justice Finlay refusing leave to appeal against the conviction and sentence; and (3) application for leave to call further evidence. The counsel briefed for the appellant were Sir Edward Marshall-Hall, K.C., Mr. Norman Birkett, K.C., and Mr. Arthur Davis. Sir E. Marshall-Hall, however, was unable to appear owing to illness.

### Argument by Counsel for the Appellant.

Mr. Birkett said: The grounds of appeal in this case will be (1) misdirection and non-direction as to the law applicable to such a case, (2) misdirection and non-direction as to the evidence, (3) wrongful admission of evidence, and (4) that the verdict was against the weight of evidence. I am aware that your lordships are familiar with the facts of the case, but in order to make clear the arguments which I propose shortly to address to the court, I hope your lordships will allow me to state the main facts which were put before the court below on December 11th last. The appellant, Percy Bateman, was a panel doctor carrying on his practice at Deptford, and it was said in the course of the trial that he was a "slum practice." It was at any rate true that he did attend to very many poor people in that district. The deceased woman, Mary Ann Harding, was the wife of a builder's labourer, and lived in Deptford in two rooms at the top of four flights of stairs. She was about 33 years of age, she had had four children before, their ages ranging from 13 to 4, and the evidence was that hitherto she had been a perfectly healthy woman, and that the deliveries of the four previous children had been normal. She had been attended on each of these occasions by a midwife only. On July 23rd, 1924, she was thought to be approaching labour, and the midwife, a woman of many years' experience, was called in to attend to her. Certain pains, whether true pains of labour or not, had begun on the 21st and continued on the 22nd. These subsided for a time, but on the 23rd they recurred with such severity that they were thought to be true labour pains and the midwife was called in. The midwife dressed the unfortunate woman as for a confinement, and made a manual examination and discovered an obstruction preventing the normal delivery of the child. She then asked the woman which doctor she would like, as it was necessary for her to have some doctor, and she said "Dr. Bateman." Dr. Bateman accordingly was called in that night, and on making an examination found that there was indeed an obstruction, and that without question the presentation was extremely difficult. He at once administered chloroform, and used, in the first instance, forceps, but, finding that the forceps slipped, he put them away and proceeded to try and get the birth manually. He worked at this for an hour until, as the evidence showed, the sweat rolled from his face. Eventually the child was born dead. The doctor had arrived about ten, and the child was born sometime about midnight. The dead child was handed to the midwife, who placed it in a receptacle, and the doctor proceeded to take away the placenta.

Mr. Justice Salter: Was any negligence alleged by the prosecution up to that point?

Mr. Birkett: I think not. It seems difficult to see what negligence the prosecution really alleged. Up to that point, I think I am right in saying, there is, in my submission, no act of negligence that could be alleged.

The Lord Chief Justice: Up to that point?

Mr. Birkett: I desire to deal with every matter in this very difficult case, but I do not think from the summing up of the evidence that there was any act of negligence alleged up to that point.

The Lord Chief Justice: I am not so sure that that is the case. There were two acts of negligence alleged. One was that the doctor, apparently in the effort to remove the placenta, removed the whole, or almost the whole, of the uterus. The second was that, a little later the same evening, before he went

away, his attention was drawn to what he had taken from this woman, and he was startled, and made an exclamation, "I have pulled away the uterus," or words to that effect, and yet he did not on that day, or the day following, or the day after that, not indeed until five days later, send her to the infirmary. At any rate, after he had pulled away the uterus, he not only took no active steps to deal with the matter, but rather concealed the gravity of what he had done.

Mr. Birkett: If I may deal first with what occurred at the operation—

Mr. Justice Salter: The reason I interposed just now, before you came to the removal of the uterus, was because I wondered whether Sir Bernard Spilsbury and other experts called by the Crown imputed any blame to the doctor for the internal ruptures.

Mr. Birkett: I do not think they did. Certainly, up to the point in the narrative at which I had just arrived, I do not think anybody suggested, even for the prosecution, that Dr. Bateman had done anything he ought not to have done. Dr. Bateman removed the placenta and it was placed by the midwife in a chamber, and the midwife—a woman of great experience—noticed the pinkish colour of the placenta, which was particularly unusual, and she called the doctor's attention to it. The doctor looked at it and then used an exclamation. The nurse said, "What is this?" and the doctor said, "Good God; don't you know? It is the uterus." That is how it was discovered that the uterus had come away with the placenta. Then the doctor said to the midwife, "Don't say anything; give me the uterus." The uterus was separated from the placenta by the doctor, and he then wrapped up the uterus and took it away, and the placenta was in the ordinary course destroyed. The doctor then left the room and went to the husband in the other room, and said, "The child has been born dead, your wife is very ill, and I think she is going to die." The midwife, when the fact was pointed out that the woman was very ill, said she did suggest that night that the woman might go to hospital, and the doctor said, "We will see how she is in the morning." I do not apprehend from the evidence of Sir Bernard Spilsbury or any other witness for the prosecution, that so far any act of negligence is alleged against the doctor. When the prosecution says, "He brought away the uterus with the placenta," the answer of the defence is "That is true"; but nowhere, so far as my reading of the transcript of the proceedings at the trial goes, is it said that he was negligent in doing that. In that sense I think I am perfectly right in saying that, up to that point at all events, in respect to the mere surgical skill necessary in attending confinements, there was no negligence.

The Lord Chief Justice: The evidence is that the womb came away with the placenta, and that there was pulling—one would think it would need some pulling.

Mr. Birkett: It was never denied by the appellant that he had to use considerable violence. From the fact that there was a transverse presentation, and that very vital organs of the body were involved, it would be apparent that considerable violence had to be used, and the real reason why the uterus came away was that it sloughed. But no improper violence was done by the doctor to occasion this dreadful calamity. On the following morning the doctor went at 9 o'clock (after having been in attendance on the woman until an hour after midnight). He found her weak but conscious, vomiting a little, but able to speak, and he used the expression, when he was told by one of the relatives that she seemed to be a little brighter, "That is funny," indicating his surprise that, having regard to what had happened, she had rallied at all.

The Lord Chief Justice: Was there not evidence that when a discovered what had really happened he said to the nurse something to this effect: "We had better keep this to ourselves"?

Mr. Birkett: "Do not shock the relatives" was the phrase he used, and he said in evidence that he thought, after the calamity that had happened, that the poor woman would die, and he certainly believed, and acted upon the belief, that if she were moved down four flights of stairs in the condition in which she was that night she would die on the stairs.

The Lord Chief Justice: The phrase I had in mind was, in the doctor's evidence, "I don't remember the exact words I used: I said 'I think we had better keep this quiet.'"

Mr. Birkett: On the morning after the confinement the doctor found the woman a little brighter. He called again in the evening, and during the day certain medicine was prescribed for her. On the next day he again made two visits, and found her a little better in the morning, though still weak and vomiting. Then he suggested the use of an enema, and the midwife again suggested that the patient be sent to the hospital. The answer he made on that day was, "I will send her when she gets a bit better." On the following day he again visited her twice. On that day the stomach was very much swollen, which was an indication of peritonitis. On the

following day he went twice again, and found she had been brighter during the day but got worse at night, and on that day the midwife again suggested to the doctor that she might be sent to hospital. On the following day, when the doctor called, the husband asked if the wife could go to the hospital as the strain of looking after her was wearing them out. At 6 o'clock that night the husband went for the doctor, who said that an order for removal to hospital had been sent round to the house, and at 7.30 she was removed to the hospital. That was on the 28th, and, to conclude the narrative, she remained conscious for some hours, and died about 1 o'clock in the morning on the 30th, and an inquest was held on the 31st.

The Lord Chief Justice: She lived for a week after what had happened at the confinement?

Mr. Birkett: Yes. May I now just allude to the evidence which was given of cases comparable with this case by the medical witnesses? It is a very important point in my application in favour of the appellant that, I think, forty-eight hours was the longest time that any patient had lived following such a catastrophe, whereas this patient, through not being moved, lived for seven days.

Mr. Justice Salter: After the removal of the womb?

Mr. Birkett: Yes; this patient, as a result of the advice given by the appellant, lived for seven days, but after she was moved she died on the second day. Now, my lords, this is manifestly a case of very great difficulty and delicacy. It is a matter in which the feeling of the jury might quite naturally and properly be aroused to the prejudice of the prisoner, merely because of the circumstances of the case. It was, in my submission, therefore, in the highest degree necessary that the summing up of this matter to the jury, both as to the law and the facts, should make it abundantly clear what the allegations of negligence were with which the appellant's advisers had got to deal. Upon both those heads, I submit, this summing up falls short. I do not know that I need read the summing up, but I think it right to say this, that the summing up with regard to the law was to be gathered from passages which were isolated the one from the other. It was really a direction of this kind: "To convict this prisoner you must be satisfied that he was guilty of gross negligence"—here, my lords, let me say that it has been held for a considerable time that "gross negligence" does not differ from negligence at all, and the mere fact that you say "gross negligence" to a jury is no proper direction upon the law. Then there occurs the use of the term "culpable negligence"—blameworthy negligence. Having regard to the distinction between civil and criminal liability for negligence, and the great gulf which does and ought to separate the two things, it is no guidance to say to a jury that they must be satisfied that the prisoner was guilty of culpable negligence. To use another phrase employed by the learned judge—"wicked negligence"—this, again, is of no assistance on the law with regard to this matter, in view of the distinctions which properly arise between civil and criminal negligence. I think it a fair method of putting it that the case on the law was put before the jury like this: "If this was a mere mistake you ought not to convict the prisoner. You must be satisfied that it was gross, culpable, and wicked negligence." In my submission, that is not a proper direction in a case of this kind of negligence.

The Lord Chief Justice: Would it be convenient to indicate what the proper direction would have been?

Mr. Birkett: I should shrink from that, but I do wish to call your lordships' attention to the case of Reg. v. Doherty (reported in 16 Cox, Crown Cases, page 306)—

Mr. Justice Salter: What was the case cited by the learned judge [Mr. Justice Shearman] in his summing up?

Mr. Birkett: My researches have not led me to discover the passage which he did cite. I was not in the court below when this case was tried, and no reference was given in the transcript; it may very well be that the learned judge was citing from memory. But I do invite your lordships' attention to this case of Reg. v. Doherty. The facts of that case have no application to the case now before the court, but Mr. Justice Stephen, before whom it was heard, said in his summing up: "Manslaughter by negligence occurs when a person in doing anything dangerous in itself, or having charge of anything dangerous in itself, conducts himself in regard to it in such a careless manner as to be guilty of culpable negligence." The learned judge goes on to suppose a man performing a surgical operation and, whether from losing his head, or forgetfulness, or some other reason, doing something he ought not to do, or omitting to do something he ought to do; in such a case there would be negligence.

The Lord Chief Justice: Suppose he omitted to do something he ought to have done when it had become apparent to him that a catastrophe had really happened, would it not be said, *a fortiori* in such a case that there would be negligence?

Mr. Birkett: It was assumed by the prosecution that because

Dr. Bateman did not send this woman to the hospital therefore he was negligent; but it was ignored that in the exercise of his skill and knowledge he had decided that the course he took was the best, and in this he was supported by two eminent obstetric surgeons in London, who said that what he did they would have done. Your lordships perceive the difficulty. If it is decided that as a result of acting to the best of his skill and knowledge he is guilty of culpable negligence, then I submit that the medical profession would be in a very difficult position indeed.

The Lord Chief Justice: To go back to the point you started from. The term "gross negligence" still survives. What Mr. Justice Stephen says here is that gross negligence is culpable negligence. Criminal negligence equals gross negligence, and gross negligence equals culpable negligence.

Mr. Birkett: My lord, would it be a just observation for me to say this? I appreciate what "gross negligence" and "culpable negligence" mean, but I doubt whether a lay jury does. And it was in the highest degree important that the exact bearing of phrases familiar on the lips of lawyers should be made plain to the lay jury.

The Lord Chief Justice: Does not the word "wicked" make a difference? "Wicked" is a variant of "culpable."

Mr. Birkett: I think "wicked" conveys to a layman something more than ordinary negligence. In my submission it is not a proper summing up to say that the jury must be satisfied that there is wicked negligence.

Mr. Justice Salter: What is a judge to say? Here is a great criminal lawyer who begins by using the vituperative epithet "culpable," and then proceeds to say what is culpable, and he puts supposititious cases—very strong and obvious ones.

Mr. Birkett: May I just read the words that follow those I have already quoted from Mr. Justice Stephen's judgement: "But if there was only the kind of forgetfulness common to everybody or a slight want of skill which would be met by civil damages, it would be wrong to proceed against him on criminal grounds." And he goes on: "To find culpable negligence in the present case you must" do so and so.

The Lord Chief Justice: What you get in this judgement is really the word "culpable" reinforced by illustrations.

Mr. Birkett: Just before I leave that matter I hope I may urge this. So far as my own experience goes, in the case of a doctor who has to attend patients, and, I suppose, almost every day to do things which involve life or death and certainly involve risk of lifelong injury, in my submission, when you are dealing with the negligence and the criminal negligence of a man so situated—when a precise criminal charge is laid against him, namely, the death of this woman—there is a duty in law that that negligence shall be accurately and plainly defined.

Mr. Justice Salter: There is another aspect of negligence that we must bear in mind. A man may be held guilty of negligence—certainly for civil purposes, and, I suppose, for criminal purposes also—even though he used the utmost care, if his competence is insufficient. He may take all the pains in the world and yet be guilty of negligence. That is a point which is a difficult one in this case. Mr. Justice Shearnan summed up in a very uncompromising way, as he would sum up in a civil case.

Mr. Birkett: I should also like to call your lordships' attention to the case of *Rex v. Williamson* (3 Carrington and Payne, p. 635)—a case which is very near to this case. The prisoner was indicted for manslaughter. From the evidence of the nurse it appeared that the deceased woman had been delivered by the prisoner of a male child, and two days later there was found a prolapsed uteri, which the prisoner mistook for the remaining part of the placenta. He attempted to bring away what he thought to be the rest of the placenta, and there was a rupture and the woman died. It was stated that there must have been great want of anatomical knowledge on the part of the prisoner. Lord Ellenborough, in summing up, said:

"A person in the habit of acting as a man midwife, tearing away part of the prolapsed uterus of one of his patients, supposing it to be a part of the placenta, by means of which the patient dies, is not indictable for manslaughter unless he is guilty of criminal misconduct arising either from the grossest ignorance or from the most criminal inattention. One or other of these is necessary to make him guilty. It does not appear that in this case it was any want of attention, and it would seem that having placed himself in a dangerous situation he became shocked and confounded. . . ."

The Lord Chief Justice: Those observations are clearly directed to the mistake which the surgeon made when he believed a prolapsed uterus to be the remnant of the placenta, and used force. The judge would hardly have used such expressions about a case where the surgeon, having done that, and having discovered the nature of what he had done, refrained from taking serious and proper steps.

Mr. Birkett: The case is quite distinct in that matter. But my submission is that in a case involving a medical man and his skill and judgement, not the positive nor the comparative but the superlative might properly have been used in order to make it abundantly clear to the jury what was meant by criminal negligence.

The Lord Chief Justice: According to that, you must not say "gross," but you may say "grossest"; you must not say "culpable," but you may say "most culpable."

Mr. Birkett: I do not enter into those refinements, my lord, but I point out that Lord Chief Justice Ellenborough in the case I have quoted says that to substantiate the charge the prisoner must have been guilty of criminal misconduct arising "either from the grossest ignorance or from the most criminal inattention." There is no ambiguity about that language.

The Lord Chief Justice: Is not our standard of negligence based on a series of decisions by juries?

Mr. Birkett: The principle upon which they proceeded was, of course, the duty of taking reasonable care.

The Lord Chief Justice: They decided in relation to all the circumstances what was reasonable care.

Mr. Birkett: I would not quarrel for one moment were this an ordinary civil case. It was for the jury to deal with the question of what was reasonable. But when a medical man is tried on a criminal charge, then I submit that the province of the jury must be based upon the clearest and most accurate description of the law to which they are to apply their judgement. [Counsel here referred to another case, an indictment for manslaughter consequent upon an operation, in which Lord Chief Baron Pollock delivering judgement concluded with the words, "If a person *bona fide* and honestly exercising his best skill to cure the patient performs an operation which causes the patient's death he is not guilty of manslaughter."]

Mr. Justice Salter: If that is a complete exposition of the law it appears to give the go-by to any question of standard of skill. If he does his best it is said that he cannot be guilty of manslaughter. Sir Edward Marshall-Hall said much the same thing to the jury in this case, and, rightly or wrongly, Mr. Justice Shearnan challenged that.

Mr. Birkett: Perhaps it would be convenient if I read the passages in the summing up to which exception is taken.

The Lord Chief Justice: In this case which you have cited what was being criticized was the operation itself. There was no such subsequent history as you have in the case which is the subject of the present application.

Mr. Birkett: Your lordship has put to me the importance of the subsequent events. I wanted to say at a later stage that the question of negligence in the operation was a matter which ought never to have gone to the jury at all. Indeed, the fact that that was not withdrawn from the jury would be a sufficient ground for me to have leave to appeal.

#### Application Granted.

After consultation with his colleagues on the bench,

The Lord Chief Justice said: Mr. Birkett, what you are asking for now is leave to appeal. We all think, after your able argument, that there is a question of substance to be considered here, and therefore we will grant leave to appeal. I notice that in your application there is a reference to certain further evidence.

Mr. Birkett replied that in the court below two obstetric surgeons of very high standing were called, and the additional evidence that was sought to be called now was merely another opinion of the same rank. The medical profession was very much exercised about this matter and was anxious to leave no stone unturned to put the true case before the court. The happenings in this case had been of immense interest to the medical profession, and considerable research had taken place, as a result of which one or two matters had been elicited from eminent people which, had they been known at the time, would have been very convincing in defence of Dr. Bateman. It was accordingly felt that the door might be left open for such expert evidence to be given before the Court of Criminal Appeal.

The Lord Chief Justice: We do not at this stage give leave to call further evidence. I gather that you have not looked into the matter as fully as you wish to do. If, after careful consideration, you do come to the conclusion that it would be right to have a witness here who may be called if the court so orders, that is a matter for your discretion; but when you have already called two eminent witnesses there is not much point in calling a third unless there is some special reason.

This concluded the proceedings. It is understood that the appeal will be heard on Monday, February 9th.

## Obituary.

**CECIL CLARKE, M.D., M.R.C.P.Lond.,**  
Assistant Physician, Bristol General Hospital.

By the death of Cecil Clarke at the age of 39 the Bristol Medical School has lost one of its most brilliant students and a teacher of whom great things had been justly expected. He graduated M.B., B.S.Lond. in 1908 and M.D. in 1910; he took the diploma of L.R.C.P. in 1913. After a triumphant career through his own school, in which he took all the available prizes, he held two resident appointments in Bristol and then went on to the Hospital for Consumption at Brompton, being successively assistant resident medical officer, house-physician, and assistant in the pathological department there. During this time he was attacked by pleurisy and was laid up for some months. After some post-graduate work in London he joined a Red Cross unit serving with the Bulgarian army in the second Balkan war, and received various Bulgarian and British decorations. A sojourn at Dresden, where he learnt much from Professor Schmorl, brought him to the verge of the European war; indeed, on its outbreak, he hurried back from Vienna, whither he had just gone, to Dresden, escaping ultimately into Holland. He joined the R.A.M.C., and was detailed for bacteriological work, first in Belgium and later in Macedonia. In each field he rendered excellent service—in the detection of typhoid among civilians in the former and on the histopathology of malaria in the latter. He was invalided home from Macedonia on account of chronic bacillary dysentery, but went out once more to France, and insisted on service with a battalion, in spite of poor health. After the armistice he was sent home to laboratory work at a hospital for officers, and returned to Bristol on demobilization in 1919. There he became medical registrar and then assistant physician to the General Hospital, and physician to the Queen Victoria Jubilee Convalescent Home. But his health was never quite normal, and in 1922, after a long but obscure illness, a septic appendix was removed. This had rekindled his pulmonary infection, and from that time onwards his days were spent in a most courageous fight against a slowly progressive infection. Even to the time when, only three weeks before his death, he left England hoping for a good winter abroad, he had never abandoned the prospect of a return to his hospital work.

If Cecil Clarke had lived he would have done great things. His intellectual powers were high. He had an intuitive capacity for discerning the truth in scientific work, as well as a wide knowledge of medicine and pathology. Moreover, he was well instructed in the English classics, a keen naturalist, and an amused and interested observer of men and things. He was, therefore, a genial companion and a delightful correspondent. But it is by his sturdy courage that he ought to be longest remembered. He said little, even to his intimates, of the disappointment that his failure in health meant to him, but set himself to endure and to overcome; and though victory over his disease was denied him his spirit rose victorious over all his trials and disappointments.

He married, in October, 1919, Miss Nora Martin, who cared for him with the greatest devotion throughout his long struggle. On January 2nd, 1925, most of his hospital colleagues, as well as many others, attended a memorial service, held at St. Paul's Church, Clifton. Those who had known him and worked with him must always feel a deep and sincere regret that his great gifts were exercised for so short a time on behalf of his school and his profession.

**ARTHUR GEORGE SHURLOCK, M.A., M.B., B.Ch.,**  
D.P.H.Camb.,

Assistant County Medical Officer, Hampshire.

THE death of Dr. A. G. Shurlock at the early age of 50 robs the public health service of one of its most promising junior members. He was the son of Mr. F. W. Shurlock, Principal of Derby Technical College, and was born at Bristol on July 9th, 1894. After education at Derby School and Derby Technical College he proceeded with an open scholarship to Jesus College, Cambridge, where he was a

scholar and prizeman, and obtained a first class in the Natural Science Tripos, Part I. Subsequently he was awarded a senior entrance scholarship in science at St. Bartholomew's Hospital. He became qualified in 1918, at once taking a commission in the army. After some service in France he was appointed a pathologist to the British Expeditionary Force, and served in three of the large military hospitals. He relinquished his commission (captain R.A.M.C.) in October, 1920. He returned to St. Bartholomew's Hospital, graduated M.B. and B.Ch.Camb. in 1921, and held house-physicianships at the City of London Hospital for Diseases of the Chest and the East London Hospital for Children.

During his studies for the diploma in public health he attracted special attention by his conspicuous ability in and enthusiasm for preventive medicine, and as soon as he had obtained his diploma he was appointed (1922) assistant county medical officer for Hampshire. His official work was of a very high order, and everyone anticipated that he was destined for a conspicuous position in the public health service. After two years' service, however, he developed the fatal malady which, after three months' painful illness, ended his life. His life in Hampshire was extremely happy. His enthusiasm for public health found full scope in the wide preventive activities of county council work, and as a keen naturalist he was able to pursue his hobby in ideal surroundings in the New Forest. He was reticent and reserved, but was much liked by everyone who knew him. As an officer of clinics and maternity centres he was extremely popular.

The news of the death of Dr. J. C. MARTIN of Portrush, on January 31st, was received with great regret both by the profession and the public in Northern Ireland. Dr. Martin, who was born in 1857 in India, where his father was in the Civil Service, received his medical education in Trinity College, Dublin, and soon settled in Portrush, co. Antrim, the best known of the watering-places of the North of Ireland. He rapidly acquired a large private practice, and was one of the founders of the Coleraine and the Portrush Cottage Hospitals, and was a member of the staff of both, became coroner for North Antrim about twenty years ago, was a magistrate for the county, chairman of the old Portrush Town Commissioners, besides holding numerous minor appointments, and was an original member of the Portrush Golf Club. He was a great favourite with the profession, the inhabitants of Portrush, and with the huge influx of visitors each summer; his loss will be greatly felt. His professional reputation was high, and he was noted for his surgical skill; he was an ex-President of the North of Ireland Branch of the British Medical Association. Much sympathy is felt for his widow and family; his son lately settled in practice in Portrush.

## The Services.

### ROYAL ARMY MEDICAL CORPS. Successful Candidates.

THE War Office announces that of the candidates who presented themselves for the competition for commissions in the R.A.M.C., held in London last month, the following were successful:

T. A. J. M. Dodd, M.B., B.Ch., Oxford University and St. Bartholomew's Hospital; \* R. A. Bennett, M.B., Ch.B., Edinburgh University; \* W. D. Speedy, M.B., B.Ch., Trinity College, Dublin; \* J. N. Atkinson, M.B., B.Ch., Trinity College, Dublin; \* W. A. D. Drummond, M.R.C.S.Eng., L.R.C.P.Lond., University College, Dundee; \* J. D. Corner, M.B., Ch.B., Edinburgh University; W. H. Carter, M.B., Ch.B., D.P.H., Edinburgh University; J. G. E. Vachell, M.B., B.Ch., Cambridge University and St. George's Hospital; J. T. Smyth, M.B., B.Ch., Queen's University, Belfast.

\* These candidates, being in possession of certificates obtained in the Officers' Training Corps, were awarded service marks under paragraph 85 of the Regulations for the Officers' Training Corps.

### TERRITORIAL DECORATION.

THE KING has conferred the Territorial Decoration upon the following officers of the R.A.M.C. under the terms of the Royal Warrant dated October 13th, 1920: Lieutenant-Colonel (Brevet Colonel) Thomas B. Wolstenholme, O.B.E., and Majors Harold W. Read and Edmund Alderson, D.S.O.

## Universities and Colleges.

### ROYAL COLLEGE OF PHYSICIANS OF LONDON.

An Annual quarterly comitia of the Royal College of Physicians of London was held on January 29th, when the President, Sir Humphry Rolleston, was in the chair.

#### Membership.

The following successful candidates were admitted as Members:

Wallace Wright Adamson, M.B. Glasg., Wilfrid Henry Waller Attlee, M.D. Camb., Francis Joseph Benjamin, M.D. Durh., Frank Brockington, M.D. Lond., Charles Ritchie Burns, M.D. New Zealand, Ernest M. D. Calvert, M.D. Edin., Lord Jones.

#### Licences.

Licences were granted to the following 206 candidates who had passed the required examinations and conformed to the by-laws and regulations:

M. Absé, J. D. Allen, G. T. Allerton, C. A. Amesnr, \*Kathleen J. Atkinson, \*Margaret A. Bannerman, W. D. Beck, C. E. G. Beveridge, O. P. Bewers, \*Anna M. V. Bonhote, V. H. Bochhyer, W. A. Bourne, R. N. Brandwood, S. Brest, H. P. Brower, D. A. Briggs, D. J. Brims, R. J. Brocklehurst, T. H. P. Brooks, \*Margaret H. Brown, W. A. Browne, \*Olive B. Buckley, W. H. Cameron, A. F. Chalkey, \*Gwendoline Chave, H. F. Chillingworth, G. F. Chissell, L. Chodorsky, J. Chronnell, H. A. Clegg, A. V. Clemmey, \*Doris M. Collins, L. N. R. Comty, L. C. Cook, \*Margaret I. B. Cowling, C. P. Craggs, \*Dorothy E. Crellio, J. Currie, M. Cutner, \*Gweneth M. Daniel, \*Annie E. C. Davies, A. D. Davies, J. R. Davies, W. H. Davies, A. R. Davidson, \*Charlotta D. N. De Wilde, G. E. Ellis, O. M. Ellis, \*Mary H. Elmitt, C. W. Evans, J. Evans, N. B. Farman, J. T. Fathi, L. Fathi, C. P. Fernando, M. G. Fitzgerald, \*Dorothea C. Forbes, G. R. Ford, W. S. Fricker, T. M. Frison, O. P. Giles, G. D. Gordon, H. W. Gordon, B. A. Grant, F. N. Green, A. L. Greenwar, D. L. Greig, J. M. Hall, \*Constance I. Ham, G. Hamada, J. E. S. Hamilton, C. H. Hampshire, A. W. Hanlon, Hans-Raj, \*Frede D. F. C. Hastlow, N. H. R. Hatfield, S. Helberg, A. Helmy, \*Freda K. Herbert, E. Herzberg, A. E. Hill, C. H. Hilliard, \*Minnie E. Hope, E. C. Hudson, D. B. Hughes, \*Katherine E. W. Hulse, O. R. Humphreys, F. S. Hunter, O. L. Hutchinson, \*Joy Hwa, S. Hyman, \*Elizabeth Jacobs, \*Kate D. James, E. J. Jenkins, C. W. W. Jeremiah, F. Kibble, C. T. London, M. Linc, W. H. \*Catherine B. McArthur, S. McClements, \*Dorothy F. McIntosh, J. H. Macpherson, \*Helena M. J. McQuaid, R. G. Maliphant, J. P. Marsden, G. R. Marshall, E. L. Martin, A. W. C. Mellor, C. P. Miller, F. C. Miller, G. J. Morris, C. F. Morrison, A. M. Murray, W. R. Nash, \*Margaret I. Neal, E. L. Newell, R. A. Newson, H. W. Nicholson, J. A. Noot, R. A. Norman, J. N. D. O'Rafferty, \*Evelyn D. Owen, G. W. C. Parker, A. E. Parkes, W. Parry-Jones, R. Paton, V. Patrick, F. L. Patterson, \*Gladys L. Pearson, A. D. Pegg, \*Gwyneth M. Pennant, H. C. Pierce, C. P. Pinckney, C. J. Polson, L. W. Proger, D. C. Prowse, R. S. Pyrah, V. I. Raman, C. Rankin, M. D. Rawkins, J. T. Rees, \*Olwen M. Richards, J. T. C. H. Robinson, C. F. Rowelsham, K. G. W. Saunders, S. D. Seb, \*Frances E. Smith, \*Sylvia M. T. Smith, A. D. Soares, R. H. Southall, I. P. Spurrell, \*Ethel L. A. Stamborg, B. G. Staniland, \*Ruby O. Stern, D. D. S. Stewart, F. E. J. Thomas, J. D. S. Thomas, W. Thrower, T. G. Tresidder, E. A. Trushon, L. C. D. Van der Borgt Walker, R. A. Walsh, Larna H. Wa Wells, J. Willis, F. L. White, C. E. R. Williams, H. R. Williams, D. H. M. Worth, C. L. Worthington, \*Annie Yoffa, G. C. Young, J. C. Young.

\* Under the Medical Act, 1875.

#### Diplomas in Special Subjects.

Diplomas were granted, jointly with the Royal College of Surgeons, to 21 candidates in Public Health, 21 in Tropical Medicine and Hygiene, 8 in Psychological Medicine, and 6 in Laryngology and Otology. (The names were printed in the report of the meeting of the Council of the Royal College of Surgeons of England, January 17th, p. 142).

Medicine and Surgery were granted, in conjunction with the Royal College of Surgeons, to the following successful candidates:

F. Abbey Wiesener, R. G. Banks-Smith, R. R. Bickford, W. S. Burr, T. D. Gordon, E. N. Hughes, K. H. Kamakaka, A. P. McLeod, A. D. Shroff.

#### Appointments.

On the nomination of the Council the following were elected Councillors: Dr. Phear, Sir St. Clair Thomson, Dr. Bedford Pierce, and Sir Leonard Rogers; and, to take the place of Dr. Drysdale (for two years), Sir Walter Morley Fletcher.

Sir Francis Champneys was re-appointed a representative of the College on the Central Midwives Board.

Sir George Newman was appointed a representative of the College on the executive committee of the Imperial Cancer Research Fund, vice Dr. Sidney Martin, deceased.

The President announced that he had appointed Dr. Edwin Bramwell to deliver the Bradshaw Lecture this year, and that the Council had appointed Professor Topley, M.D., F.R.C.P., to deliver the Milroy Lectures next year.

The resignation of Dr. Drysdale as a member of the Council was accepted.

#### Admission of Women to the Fellowship.

The following alteration in the by-laws was resolved:—

That the existing By-Law No. 19, be repealed, and the following by-law be substituted for it:

A woman shall be eligible for admission as a Licentiate or Member of the College and for the grant of diplomas in special subjects on the same terms and conditions as a man and a woman on as a Fellow of the College and shall have the same rights in the government management and to hold any office in like manner as

So far  
in the  
be de  
tions as  
form of  
granted

as are requisite shall be made in the letters testimonial the form of licence and attached certificate and the form of diploma granted by the College.

#### on the University of London.

Sir Dr. John Fawcett were appointed Departmental Committee on the University of London.

#### Miscellaneous.

A contribution of 20 guineas to the St. Paul's Cathedral Restoration Fund was voted by the College.

Reports were received from the Committee of Management and adopted.

Books and other donations to the library, presented during the last quarter, were received; also, from Mr. C. H. Golding-Bird, a miniature bust of Dr. Golding-Bird, F.R.C.P., and also a copy of a portrait of Dr. Brinton from his son.

After some formal College business the President dissolved the comitia.

## Medical News.

THE Hunterian Oration before the Royal College of Surgeons of England will be delivered in the theatre of the College by Sir D'Arcy Power, K.B.E., F.R.C.S., on Saturday next, February 14th, at 4 p.m.

THE next meeting of the Chelsea Clinical Society will be held at the club-rooms of St. George's Hospital on Tuesday, February 17th, at 8.30 p.m., when Sir Thomas Parkinson and Mr. A. N. Thompson will open a discussion on the diseases of the climacteric period in both sexes.

THE next meeting of the Medico-Psychological Association of Great Britain and Ireland will be held on Thursday, February 19th, at the Royal College of Physicians, Queen Street, Edinburgh, under the presidency of Dr. M. J. Nolan, at 2.30 p.m. Dr. David Slight will give a demonstration of the psycho-galvanic reaction; Dr. George Gibson will read a paper on the boarding-out system; and Dr. William M. McAlister, a paper on results of treatment of general paralysis by malaria.

THE annual dinner of past and present students of the Royal London Ophthalmic Hospital will be held at the Langham Hotel, Portland Place, on Thursday next, February 12th, at 7 for 7.30 o'clock. Mr. W. T. Holmes Spicer, consulting surgeon to the hospital, will preside. Tickets (15s. each, excluding wine) may be obtained from Sir William Lister, 24, Devonshire Place, W.1.

PROFESSOR FUCHS, the well known ophthalmologist of Vienna, will shortly visit Madrid to deliver four lectures on glaucoma, cataract, sympathetic ophthalmia, and ocular tuberculosis respectively.

THE Fellowship of Medicine announces that on February 9th, at the Royal Society of Medicine, at 5.30 p.m., Dr. Andrew Balfour will show a cinematograph film on malaria, with special reference to the malarial parasite as a therapeutic agent. The second week of a three weeks' combined course in diseases of children begins on February 9th; the institutions concerned are the Paddington Green Hospital, Victoria Hospital, and the Children's Clinic. A four weeks' course is also being held during February at the St. John's Hospital for Diseases of the Skin. At the London School of Hygiene and Tropical Medicine a series of eight lectures is in progress on Tuesdays and Thursdays, and the second week of the course in venereal diseases at the London Lock Hospital will begin on February 9th. During the last fortnight in February there will be a course in general medicine and surgery and the special departments at the Prince of Wales's General Hospital, Tottenham. In March courses will be held in diseases of the chest at the Brompton Hospital; medicine, surgery, and gynaecology at the Royal Waterloo Hospital; infectious fevers at the North-Eastern Fever Hospital (Tottenham); gynaecology at the Chelsea Hospital for Women; and an intensive course in general medicine, surgery, and the special departments at the Royal Northern Hospital, with which is associated the Royal Chest Hospital. Copies of the syllabus of these courses may be obtained from the Secretary of the Fellowship at No. 1, Wimpole Street, W.1.

THE Central Association for Mental Welfare is arranging a special three months' course for teachers of mentally defective, dull, and backward children, to be held in London from May 7th to July 25th. The course will include lectures on normal and abnormal psychology, methods of teaching, demonstrations in speech training, manual work, and the social and legal aspects concerned. Further information may be obtained from the office of the association, 24, Buckingham Palace Road, S.W.1.

By an order dated December 31st, 1924, and issued on January 30th, 1925, the Home Secretary has added to the list of conditions which must be notified in compliance with Section 73 of the Factory and Workshop Act, 1901: (1) poisoning by carbon bisulphide; (2) aniline poisoning; and (3) chronic benzene poisoning. The notice must specify the name and personal address of the patient and the disease from which in the opinion of the medical practitioner he is suffering. For this notification the medical practitioner is entitled to a fee of 2s. 6d. Failure forthwith to send a notice renders the practitioner liable to a fine not exceeding 40s.

The private wards in Westminster Hospital are, with the permission of the Prince of Wales, president of the hospital, to be named "The Prince of Wales Wards." The new ophthalmic wards are to be named the "Wolfe Barry Wards," in memory of Sir John Wolfe Barry, chairman of the house committee from 1899 until his death in 1918.

BEGINNING with the January issue, the *Revue de Médecine* will contain short memoranda, rather than the larger original articles published hitherto. It will be mainly devoted to abstracts of the principal medical publications in France, Great Britain, Germany, Spain, and Italy which have appeared during the previous month, and will so become more definitely a review of recent medical literature.

The fifth congress of French-speaking pediatricists will be held at Lausanne in 1926 under the presidency of Dr. Tallens, professor of children's diseases in the University of Lausanne.

THE January issue of the *Journal of the Outdoor Life* is essentially a Trudeau memorial number, being issued in connexion with the fortieth anniversary of the foundation of the famous sanatorium at Saranac Lake, New York. We gave an account of recent additions to the institution on June 14th, 1924 (p. 1062), and this anniversary number of the *Journal*, founded in connexion with the sanatorium in 1903, gives very full details of the work that has been carried on at the sanatorium. Personal recollections are supplied by several contributors, including Dr. Lawrason Brown, the originator of the *Journal*, at first an assistant resident physician and a joint builder of the sanatorium organization. A short article deals with Robert Louis Stevenson, who came to Saranac Lake in the autumn of 1887, and whilst there wrote some of his best essays, including *Pulvis et Umbra*, *The Lantern Bearer*, *A Christmas Sermon*, and some portions of *The Master of Ballantrae*. The issue is well illustrated.

The annual medical congress known as the "Journées médicales de Bruxelles" will be held at Brussels from June 21st to 24th. Further information can be obtained from the general secretary, Dr. Beckers, 36, rue Archimède, Brussels.

THE fourth International Congress of Industrial Medicine will be held at Amsterdam in September, 1925. Further information can be obtained from the general secretary, Dr. Brocx, 55, Plecke de Hoehstraat, Zimmer 54, Amsterdam.

THE twenty-ninth congress of French-speaking neurologists and alienists will be held in Paris at the end of May, 1925, under the presidency of Dr. Anglade, when the following papers will be read: Late recovery from mental disease, by Dr. Robert; familial infantile encephalopathies, by Dr. Crouzon; legal medicine and states of mental torpor, by Dr. Briand.

DR. DEVÉ has been nominated professor of clinical medicine in the medical school at Rouen.

A sudden malaria epidemic in Java is reported to have caused 1,000 deaths.

WITH its January issue the *Canadian Medical Association Journal* enters the fifteenth year of its publication as the official organ of the association. During the past ten years it has doubled the number of its reading pages and increased their size. In a foreword to this issue reference is made to the visit of Sir Jenner Verrall and Dr. Alfred Cox last year, and it is noted "that after free discussion a form of affiliation was arrived at, by which our association, without losing any of its individuality, becomes affiliated with the parent society, and through it with the medical profession in all the sister dominions of the empire. This will confer certain privileges upon our members. We hope that this action may lead to many pleasant interchanges between our association and the profession in Great Britain, and in the other dominions." The annual meeting of the Canadian Medical Association will be held at Regina, from June 22nd to 26th.

## Letters, Notes, and Answers.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—not necessarily for publication.

Communications intended for the current issue should be posted so as to arrive by the first post on Monday or at latest be received not later than Tuesday morning.

THE telephone number of the British Medical Association and British Medical Journal is Gerrard 2630 (Internal Exchange). The telegraphic addresses are:

EDITOR of the British Medical Journal, Aitiology Westrand, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London.

MEDICAL SECRETARY, Mediscern Westrand, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Articulus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Rindall Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

ALKALIS AS ADJUVANTS TO ACTION OF INTESTINAL ANTISEPTICS.

DR. L. WHEELER (London) writes: I should be glad to learn of any experience in the use of an alkali (sodium bicarbonate), given before meals, improving the action of an intestinal antiseptic administered after meals.

### INCOME TAX.

Board and Lodging of Assistant.

"R. M." is an outdoor assistant not receiving any allowance from his principal for board and lodging. If the latter were to pay the landlady's bill each month, giving the assistant the balance of his salary, could "R. M." return that balance as his income for tax purposes and the employer deduct the full amount as a professional expense?

\* It would not be correct unless a real alteration were made in the terms on which "R. M." is employed—for instance, suppose the gross salary be £x and the annual amount of the board-lodging expenses be £y, then, so long as the employer is liable under the terms of engagement to pay "R. M." £x, that is the amount of his liability, whether it be wholly paid to him personally or partly to his landlady. But if an alteration be made in a binding manner in these terms, so that the employer is bound to pay "R. M." £x-£y only and to provide him with board-lodging, then the latter is liable in respect of £x-£y only, and the employer can treat as a professional expense £x-£y plus the actual cost of the board-lodging which he provides.

### LETTERS, NOTES, ETC.

#### MONEYLENDERS.

In the *Times* law reports for January 25th is a note of a case heard before Mr. Justice P. O. Lawrence in the Chancery Division. It appears that a moneylender had obtained judgement summonses against two civil servants who appeared before the court. In reply to the judge one of the debtors said that they had borrowed £15 each, and the judge remarked that the amount had swollen to £54. An order was made for payment of £1 a week in one case and 10s. in the other. Addressing the debtors the judge said, "Pull yourselves together and get out of the hands of moneylenders, or it will wreck your whole careers." It appears to be the general experience that at the present time moneylenders are very active in issuing circulars offering to lend money. One rather senior member of the profession has sent us such a circular he received the other day; it contains the statement—"We may add that for a considerable time we have specialized in accommodating persons on exceptionally low terms." The Mr. Justice Lawrence appears to risk attaching to the acceptance of such offers.

#### CORRECTIONS.

DR. JAMES COOK wishes to correct an error in his letter on puerperal infection, published last week (p. 236). His percentage of puerperal infection cases is 0.5 per cent.—not 0.05.

An error occurred in *Epitome*, para. 130, of our issue of January 31st. The name of the fourth of the joint authors should have been given as J. S. B. Stophord.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 34, 35, and 38 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 69.

## A British Medical Association Lecture

ON

## SOME CONSIDERATIONS OF IMMUNITY

FROM THE STANDPOINT OF GENERAL

MEDICINE.\*

BY

T. J. MACKIE, M.D., D.P.H.,

IRVINE PROFESSOR OF BACTERIOLOGY, UNIVERSITY OF EDINBURGH.

THE subject of immunology has become one of the most technical and specialized in the whole field of medicine; and the general medical worker, in attempting to comprehend the principles and mechanism of immunity, must frequently be nonplussed by the complexity of data and intricacy of theory pertaining to this branch of medical knowledge.

If any justification is required for the subject of this lecture, it is the need for some review of immunity from the standpoint of everyday medicine. Experimental immunity has, of course, claimed primary attention with signally successful results, and highly important practical applications have arisen out of this work; but the subject of immunity should make an even more cogent appeal to the practitioner than that suggested by the successful application of experimental immunity.

Infective disease, as it occurs in man, is essentially a biological process which represents the predatory aggression of micro-organisms towards one of the higher animals in the natural struggle for existence; and just as all living things have adapted themselves to resist their aggressors, so immunity from infective disease is merely an adaptation which enables an animal to maintain its life in spite of the constant attack of micro-parasites. Thus the animal body has become provided in its physiological evolution with a normal immunity mechanism which affords it some relative protection from micro-organisms generally. This resistance in any species is greater towards some parasitic organisms than others; the former are usually incapable of attacking the tissues, the latter are the recognized pathogens for that species. Without this normal mechanism no animal could exist in our world, which abounds in microbe parasites.

Apart from purely biological considerations, we have only to reflect that recovery from microbic disease in the absence of a specific remedy, after the parasite has overcome the initial defences, depends on the further adaptation of the immunity mechanism, that the fate of the individual is a function of this adaptation, and that the physician in directing the general treatment is empirically attempting to facilitate the process. This is only a reiteration of the Hippocratic doctrine of the *vis medicatrix naturae* with an immunological interpretation.

Thus the practitioner of medicine is in reality the best observer and recorder of the external manifestations of this mechanism, its initial failure evidenced by the occurrence of infection, its successful adaptation with recovery from the disease, and often, unfortunately, its second failure and the destruction of the host. The problems of immunity, therefore, are not matters for research and discussion by special workers in this branch only, but relate to the ordinary affairs of general medicine and surgery. The practitioner is just as much concerned with the mechanism of immunity as with that of the vascular system.

## THE NORMAL DEFENCES.

The normal defensive system merits first consideration—that is, the means whereby infection is resisted without artificial intervention. It must be obvious that this function is a variable one—depending on race, family, sex, age, and individuality, and varying from time to time even in the same person as a result of known and unknown conditions that affect the individual. The occurrence of a rapidly fatal streptococcal septicaemia following even a minor superficial wound cannot always be explained on the basis of bacterial virulence, and is a striking demonstration of an adverse variation in resistance on the part of the

individual. But even in these days of highly developed surgical technique and treatment one cannot but marvel at the natural immunity of the tissues following trauma; and it is well known how, in the case of certain epidemic diseases, a proportion of persons to whom the virus gains access actually resist infection, or at least the spread of the organism in the tissues—for example, epidemic cerebrospinal meningitis. Microbic invasion of the tissues by those commensal but potentially pathogenic organisms that inhabit the skin and various body cavities is almost inevitably a frequent occurrence even in the normal person, but how infrequently does infection result in this way! The invading organism is rapidly destroyed and eliminated. On the other hand, in the case of a *B. coli* pyelitis, coliform bacilli invading the blood stream or lymphatics from the bowel lumen, in some way, overcome the natural defences and established themselves in the kidney.

It is apparent that further knowledge regarding the various influences affecting the normal immunity would be a great asset in preventive medicine.

The skin epidermis, with its thick and compact epithelium, is, in most cases, if intact, a mechanical obstacle to bacterial invasion. The epithelium of mucous membranes, however, does not provide this physical protection, though the mucous secretions exert an extremely important defensive function both mechanically and chemically. Thus the acid secretion of certain mucous membranes (for example, the stomach) is definitely antiseptic, and the importance of the acid factor in the gastric juice as a barrier to infection is not to be underestimated. For example, the likelihood of the typhoid bacillus passing the stomach is greater if the acid secretion is deficient owing to some condition interfering with the healthy function of the organ, or if the stomach is empty and the secretion is in abeyance (Cornwall and La Frenais).

Apart from chemical antiseptic effects, the secretions of the body possess definite bactericidal properties. The exact nature of these is not yet fully understood. An interesting contribution to our knowledge of this subject is due to Fleming, who has shown how various secretions and tissues contain a bacteriolytic agent ("lysozyme"). In any case interference with the normal secreting function of the mucous membranes means a distinct weakening in the body's defence.

In this connexion we have to consider the local resistance or susceptibility of particular superficial tissues towards certain bacteria, so that successful infection may only occur through definite avenues—for example, the mucosa of the genitals in the case of the *Spirillum pallidum* and gonococcus (though extragenital infections are not infrequent), the mucosa of the nasopharynx in the case of the meningococcus, etc. The cholera vibrio injected subcutaneously is killed locally, and cannot attack the body by this avenue. The oesophageal mucosa is obviously resistant to the diphtheria bacillus. Pathogenic bacteria may exhibit a selective affinity for special tissues: the typhoid and dysentery bacilli both invade the body through the alimentary tract, but the former selects the lymphoid tissue of the small intestine, the latter the mucosa of the large bowel. Local tissue susceptibility, on the one hand, and resistance on the other, exert an important influence on the processes of disease.

Once the parasite passes the superficial barrier and enters the tissue spaces it has to encounter a continued resistance—the phagocytic action of the leucocytes, endothelial cells, and probably certain other cells, and also the bacteriostatic and bactericidal action of the blood plasma and lymph. Little need be said with regard to the power of the phagocytes to ingest and eliminate micro-organisms and other foreign substances—the phenomenon is so well known. But some reference may be made to the adverse properties of the blood plasma. It has long been known that normal blood serum exerts an effect on bacteria, rendering them more susceptible to phagocytosis, and this has been designated bacteriostatic or opsonic action. It is apparently due to an undefined labile constituent of the serum—normal opsonin—which has no direct influence on the vitality of bacteria, but plays an essential part in their destruction by leucocytes. Blood serum is also bacteriolytic or bactericidal, and this effect has been accepted as due to

\* Delivered to the Dumfries and Galloway Division of the British Medical Association, September 25th, 1924.

an unstable substance designated alexin or bactericidal complement. This property of serum has attracted a considerable amount of attention in immunological study; but even now it is impossible to define the actual nature of complement. In many respects it resembles ferments, though it cannot be classified chemically in this way.

If the invading organisms are able to resist the immediate defences and establish for the time being a focus of infection, an inflammatory reaction may result in which larger numbers of phagocytic cells accumulate at the focus. These, along with the increased exudation of plasma, considerably reinforce the local resistance.

In analysing the initial struggle of a microbe to gain a foothold in the tissues the so-called aggressins have to be considered—that is, toxic substances produced by certain bacteria which are highly injurious to the leucocytes and so enable the invader to break down the first line of defence and increase its aggressiveness. This factor must seriously interfere with the local reaction, and the opsonin effect already referred to has been regarded by some immunologists as a neutralization of aggressin. Apart from phagocytosis, the tissue reaction affords an important protection. Thus the proliferation of fibrous tissue elements and the formation of granulation tissue walling off the focus are important protective factors. The barrier imposed by granulation tissue has been well exemplified in experiments with the tetanus bacillus and its toxin (Noctzl). Moreover, as is well known, a closed abscess may sterilize itself.

Natural immunity to particular infections may be due to the normal occurrence in the blood of specific substances antagonistic to the parasite or its toxin—that is, the so-called antibodies, which I shall refer to in more detail later. The best example of this in the human subject is the natural immunity possessed by some individuals to diphtheria, due to a specific diphtheria antitoxin in the blood. Its presence can be determined by the Schick test, where a small amount of diphtheria toxin is introduced intradermally, and the non-occurrence of a local inflammatory effect indicates the existence of t<sup>and</sup> in the blood. The opposite effect and the reaction has come to be extensively applied in preventive work, as an indication of the need for prophylactic treatment. The genesis of this natural antitoxin is uncertain, though it may be the result of a previous unrecognized diphtheria infection.

Attention has been drawn quite recently to an analogous reaction ("Dick reaction") in the case of scarlatina, based on the assumption that this disease is produced by a haemolytic streptococcus present in the throats of infected persons. It has been found that filtrates from cultures of this organism, even in high dilutions, give a cutaneous reaction like the Schick test in persons apparently susceptible to scarlatina, while those who have passed through the disease yield a negative effect. Our knowledge of this subject is still incomplete, but there is promise of further developments in treatment by the preparation of a neutralizing antitoxin analogous to diphtheria antitoxin.

D'Herelle has indicated a further immunity factor, especially in relation to intestinal infections (for example, typhoid, bacillary dysentery)—the bacteriolytic principle regarded by him as representing an ultramicroscopic parasite of bacteria (bacteriophage). In his original observations he found that broth cultures of faeces, even from normal persons, contained a filterable principle which exerted a lytic or destructive action towards intestinal pathogens—for example, *B. dysenteriae*. Whether this principle represents a parasite of bacteria or an autolytic enzyme generated in the bacteria themselves is uncertain, though recent work rather favours the latter view. The possible part played by this agent in normal and acquired resistance to infection remains to be definitely ascertained. In any case, the subject adds interest to the whole question of immunity.

It must be remembered in any consideration of normal immunity that a great factor in infection is the dose of organisms introduced into the body. In view of the undoubted potentialities bacteria have for multiplication, it may have been thought at one time that a single bacterial cell entering the tissues would be sufficient to generate the corresponding disease. We know, however, from animal

experiment, that a few bacteria injected into the body are readily disposed of by the normal defences. This function of dosage must be of the greatest importance in the genesis of disease in man. Small doses may be quite innocuous.

In studying immunity we must also consider the opposite condition, susceptibility, and the factors that predispose to infection by breaking down the normal resistance. This is a subject with which the practitioner of medicine must be familiar from his own personal experience, and merits more detailed study and analysis in general practice. Even the effects of various drugs on the normal and also the acquired immunity require investigation both from the clinical and experimental standpoints.

#### ACQUIRED IMMUNITY.

I have indicated the resistance a pathogenic microbe has to overcome before it can successfully establish itself in the tissues and some of the factors that influence this mechanism. The failure of such resistance permits the undisturbed proliferation of the organisms in the body. The existing mechanism, having failed to eliminate the parasite, requires reinforcement and further adaptation, for a much larger number of organisms have now to be destroyed if the host is to overcome the infection. In short, the struggle between parasite and host is continued with the intervention of an additional factor (or complex of factors)—acquired immunity, which means the development of new and specific resisting powers against the particular causal organism. On this factor depends the recovery of the individual in the absence of specific remedies.

The profound nature of this adaptation is evidenced by the fact that it may persist for long periods after recovery, even throughout life as in the case of small-pox. But the reverse is also true for some infections. The immunity may be transitory and decline soon after its function has been fulfilled, as in the case of pneumonia.

Acquired immunity may not always lead to the complete destruction of the causative organisms throughout the body—for instance, in tissues where for some reason the immunity influences do not affect the organisms present; it may be a "non-sterilizing" immunity, exemplified by the convalescent carrier. Thus in typhoid convalescents the bacillus may persist in the gall bladder, where it is apparently protected from antagonistic effects. Transitory non-sterilizing immunity is well seen in the case of the relapsing infections; the increased resistance resulting from the initial attack declines and the parasites still present in the body are no longer held in check, with the result that a recrudescence occurs. In the chronic infections a balance is established, the host being unable to eliminate the parasite, the latter being unable to destroy the host. In general, acquired immunity is highly specific for the particular virus and represents a special reaction on the part of the tissues to the invading organism or its products. Most of our immunological procedures are based on the specificity of acquired immunity.

Artificial immunization, which is the outcome of experimental immunology, represents the development of this highly specialized adaptation without the individual actually suffering from the particular disease, through inoculating the virus in such modified form that it is incapable of producing serious pathological effects (active artificial immunity). The adaptation can also be effected in some cases by injecting the blood serum of an actively immunized animal (passive immunity). Passive immunity obviously depends on the transference of new substances present in the blood of an immunized animal, which constitute the specific resisting mechanism—immuno bodies or antibodies.

Active immunity is more lasting than passive immunity, owing to the fact that the tissues have increased their resistance and are producing antibodies by some intrinsic change, whereas in passive immunity antibodies are supplied without tissue activity. Active immunity is, however, slower in development. Thus the latter is mainly applicable where it is necessary to confer an immunity without delay for a short period, as in emergency pro-

phylaxis by diphtheria antitoxin. On the other hand, in the case of those likely to be exposed to diphtheria over a considerable period of time and exhibiting susceptibility to the Schick test, active immunization with diphtheria toxin neutralized with antitoxin ("toxin-antitoxin immunization") is indicated. The antitoxin in this case is merely introduced to obviate the injurious effects of the toxin. The thorough combined application of the Schick test and toxin-antitoxin prophylaxis has proved a valuable procedure in the prevention of diphtheria.

The phenomenon of passive immunity clearly proves that in some cases acquired resistance is due to serum antibodies. The properties of these substances have been extensively studied, but we still know little regarding the process of their development. Though they are demonstrable mainly in the blood they are essentially tissue derivatives, and result from some chemical interaction between the cell and the protein substances contained in the parasite or its products ("antigen"). It may be noted here that, apart from antibacterial immunity, other cells and substances act as antigens—for example, red blood corpuscles, blood serum, animal venoms, etc. Certain of these antibodies are effective by neutralizing the bacterial toxin, others are antibacterial or antagonistic to the bacteria themselves. The antibacterial antibodies are somewhat diverse in their action. One type may, under certain conditions, produce actual bactericidal effects, but certain antibodies do not directly affect the vitality of the microbe though producing obvious effects, such as clumping or agglutination. Moreover, bactericidal action by antisera is not entirely due to the new substance but to the combined effect of the antibody and the normal alexin or complement of the serum. It has been claimed that the antibody sensitizes the organism, as it were, to the bactericidal complement and brings more complement into contact with the antigen than would occur without this intervention (Muir). Bactericidal action by immune bodies is therefore a complex process involving additional factors, and is not a direct effect as in the neutralization of toxin by antitoxin. While the passive immunity produced by the injection of diphtheria antitoxin and certain other antitoxic serums supplies striking proof of artificial immunization by antibodies, it must be acknowledged that animal serums containing other types of antibodies have proved less effective as therapeutic agents. It must be noted also that the obvious immunity reaction—which can be demonstrated *in vitro* by antibody effects, bacteriolysis, agglutination, etc.—may by no means represent the complete immunity mechanism. Unknown factors may contribute to acquired immunity. Immunity may occur in the absence of the recognized antibodies. Moreover, certain immunity reactions cannot be regarded as sure criteria of immunity. In fact, it has been suggested that antibody production may simply be a subsidiary result in the processes which underlie immunity (Browning): Thus the agglutinating antibody which clumps the homologous organism (agglutinin), being one of the most readily demonstrable of antibodies in laboratory experiment, has been accepted in the past as a criterion of immunity even from the quantitative standpoint; but there is now some disinclination to rely on this reaction as an index of immunity. While such antibodies may not correspond quantitatively to actual immunity, they are undoubtedly indicators of the reaction of the tissues to alien substances, which is the essence of acquired resistance. In the case of animals, of course, the sure test of acquired immunity, if carefully controlled, is by protection experiments, where the immunized animal is shown to possess a greater resistance than normal animals. This method is inapplicable in man, and we have to fall back either on statistical methods, which may introduce possible fallacies, or on the demonstrable immunity reactions, which are, quantitatively at least, uncertain indicators.

Apart from the immunity factors which bring about the destruction of micro-organisms, the occurrence of what has been called antiblastic immunity—that is, resistance due to inhibition of the growth of bacteria—merits some reference. Organisms invading the tissues utilize the available food material by their digestive enzymes, and this preparatory ferment action probably occurs at the surface of the bacterial cell. Any interference with this process would,

of course, restrain growth and contribute to the elimination of the infecting microbe. In immunization neutralizing antihodies to the bacterial enzymes may be developed by the tissues, and these, by inhibiting the bacterial ferments, restrain the growth of the organism (Dochez and Avery).

Artificial immunization by vaccines, which are generally heat-killed artificial cultures, has come to be one of the standard procedures of general medicine for prophylaxis and treatment. Statistical proof has thoroughly established the vaccine prophylaxis of certain infections—for example, typhoid and paratyphoid fevers.

In the vaccine therapy of bacterial diseases, while the basic principle of the method is the same as in prophylaxis, the application is entirely different, and, though this form of therapy is recognized as effective in certain conditions, its failures are as obvious as its successes. The fundamental question is whether, in an infection where the tissues fail to respond to the immunizing influence of the living organisms present in the body, a subcutaneous injection of the same organism in dead artificial culture will bring about an effective specific response. The original idea that in certain chronic infections the immunizing substances of the organism were not absorbed and did not therefore provoke a general reaction, and that the vaccine would supply this want, must be seriously questioned. Vaccine therapy has usually been based on the principle of specificity, but it seems not unlikely that certain of the favourable results are due to a non-specific effect. This I shall refer to later.

Any detailed analysis of vaccine therapy is beyond the scope of this lecture, but there are certain important considerations in the specific immunizing properties of vaccines to which I might draw attention. The types of antibodies developed in response to a bacterial vaccine are, for the most part, antibacterial—bactericidal, bacteriotropic, and agglutinating—not antitoxic.

Vaccines of different organisms vary greatly in their antigenic effects as judged by antibody response. Thus a typhoid vaccine exerts a marked reaction, while the immunizing effect of the tubercle bacillus is relatively weak. The antibodies resulting from immunization also vary with different organisms. The typhoid bacillus incites the production of a specific bacteriolysin, agglutinin, opsonin, whereas, in the case of the staphylococcus, bacteriolysin production is practically absent. Bacterial species vary considerably in their immunizing properties. There is no uniformity in this respect.

We must remember that our methods of producing antibacterial immunity in man are far from fulfilling immunological ideals. Killed cultures are used for obvious reasons, but one can hardly compare the effect of injecting dead bacteria with the immunity following an actual infection. The maximum immunity or protection may only be produced by the introduction of the living virus, as has been shown experimentally in the case of certain organisms. This principle is fulfilled in the case of small-pox vaccination and antirabic vaccination. To produce immunity it may be necessary that the virus should be able to multiply to some extent in the tissues. It is likely that some bacteria only produce all their characteristic products when growing in the tissues and not in culture, and if immunity depends on a reaction to all the bacterial products killed cultures would not therefore supply the necessary stimulus. Moreover, the sterilization of cultures by heat or chemicals may destroy certain essential antigenic constituents or products.

The toxicity of vaccines is also an important practical consideration. This is well exemplified in the case of the dysentery bacilli, which are extremely toxic in vaccine form. Such effects limit the doses that can be conveniently given. Toxicity can, of course, be reduced by using sensitized vaccines (where the ordinary vaccine is treated with a specific antiserum). The so-called detoxicated vaccine, in the preparation of which the toxic element is removed by chemical separation, undoubtedly obviates this difficulty, but the antigenic value of such preparations seems doubtful (Davidson).

On general principles, therefore, it is essential, in order to produce the necessary stimulus, that the virus should differ as little as possible from its natural condition. Of course, the practical difficulties in achieving such an ideal are obvious.

## DIAGNOSTIC APPLICATIONS.

One of the most interesting applications of immunology has been on the diagnostic side—that is, the use of *in vitro* antigen-antibody reactions in the recognition of infective conditions that cannot be diagnosed with certainty by clinical methods or by direct demonstration of the pathogenic agent. Their diagnostic value is a function of the specificity of antibodies for the homologous antigen, and depends on the fact that during the course of an infection these specific substances appear in the blood serum. Irrespective of whether antibodies are protective or not, they usually represent an obvious indication of the present or past occurrence of the particular organism in the body, and in this way their recognition can be utilized in diagnosis. Generally speaking, the test for an antibody depends on the availability of the homologous antigen. Thus the Widal reaction has been one of the practical results of the laboratory cultivation of the typhoid bacillus.

It has been noted how antibody production varies as a result of immunization. The same is true for the actual infection. This variation is both qualitative and quantitative. Thus the types of antibodies and their content in the serum vary considerably both in different infections and in individual cases of the same infection. The serological tests applicable in diagnosis depend on the types of antibodies developed in the particular disease; their recognizable effects on the antigen, and the facility and accuracy with which these effects can be demonstrated.

In a case of typhoid fever the agglutinin, precipitin, opsonin, and complement deviation reaction can be recognized under suitable conditions. The obvious effect is that along with the antigen it has the power of absorbing from fresh serum the normal substance called complement already referred to (complement deviating antibody). Thus the reactions of any of these antibodies might be utilized in typhoid diagnosis. The demonstration of bacteriolysis is a complicated reaction; the opsonic test, though quite practicable, is subject to great personal error; the complement deviation reaction, though relatively easy to perform, necessitates an elaborate technique. On the other hand, the agglutination reaction is easily carried out, only two reagents entering into the reaction—the patient's serum and a suspension of the bacillus—and the test is quickly completed and the clumping or agglutination is obvious even to the naked eye. Agglutination tests are the simplest to perform of all the immunity reactions, and where agglutinating antibodies are developed the reaction has been successfully utilized in diagnosis—for example, in typhoid, paratyphoid, and undulant or Malta fever. In these conditions the agglutinin content of the serum may be considerable and the reaction is quantitatively delicate.

Of course, there must be an obvious demand on the clinical side for such an indirect diagnostic criterion. There is little necessity for a serological test in an infection which can be diagnosed by more direct methods. Thus the diagnosis of diphtheria, cerebro-spinal meningitis, etc., can be confirmed in the laboratory by demonstrating the causal organism in material from the case. Even in typhoid fever, if the case is met with early enough, the most direct method is the isolation of the bacillus from the blood, and indirect methods are unnecessary.

The Wassermann complement deviation reaction is one of the most interesting of immunity tests. The original antigen aimed at for the complement deviation test in syphilis was naturally the causative organism. At that time the *Spirillum pallidum* had not been cultivated—or this test might never have been elicited—and an extract of liver from congenital syphilis containing large numbers of spirochaetes was employed. An alcoholic extract was used, and it was found that this antigen (in suitable form) along with the serum of syphilitic cases produced marked complement absorption. The specificity of the reaction for syphilis was established, but it was discovered later that extracts from normal liver, the liver and certain other organs of animals, acted also as satisfactory antigens. In short, the antigenic substance was not the *Spirillum pallidum* or its products, but the lipoids of normal tissue.

It might be said, therefore, that the Wassermann reaction is not a true immunity test. It is none the less clinically

specific for syphilis with certain limited exceptions. Investigation has tended to show that this reaction is a quantitative rather than a qualitative change in the serum. As a result of syphilis, some substance normally present in the serum—probably of antibody nature—is increased in amount, which, along with lipoids, absorbs or deviates complement.

While the Wassermann reaction involves an elaborate technique with certain pitfalls and fallacies, the serological diagnosis of syphilis is tending towards simplification by the application of the so-called Sachs-Georgi or "flocculation" reaction. This test bears almost the same technical relationship to the Wassermann reaction as an agglutination test to other complement deviation reactions. It depends on the fact that the serum in syphilis produces flocculation or precipitation of a suspension of the same lipid antigen used in the Wassermann reaction. The technique is simple as compared with that of complement deviation. Only two reagents (antigen and serum) are required and the phenomenon is easily observed.

The so-called Weil-Felix reaction presents a further anomaly in immunity. This test has proved of undoubted value in the diagnosis of typhus fever, and its discovery was quite fortuitous. Like the Widal reaction, it is an agglutination test, and depends on the development during this illness of specific antibodies (agglutinins) for a type of *Bacillus proteus* ("X 19") which has no etiological relationship to the disease. Nevertheless, the occurrence of this reaction is highly specific for typhus fever.

The significance of such anomalous immunity reactions calls for some consideration. They exemplify what we now designate "heterogeneous" or "heterophil" antibodies—that is, antibodies specific for an antigen which has no biological relationship to that acting as the immunizing stimulus. This subject has been mainly one of theoretical interest, but, as you see, it has relationships to general medicine. It was found some years ago that a rabbit injected with the tissues (for instance, kidney) of a guinea-pig developed a haemolytic antibody specific for sheep's and goat's red corpuscles (Forssman's antibody). The natural occurrence of specific antibodies in the serum of man and animals had long been recognized, and also that antibodies might have no obvious etiological significance. As a matter of fact, Forssman's heterophil antibody represents an increased output of a natural antibody in the same way as the Wassermann reaction is the result of an exaltation of a natural substance.

We have still no definite knowledge as to why such antibodies should occur. The inherent capacity to produce them may have originated far back in the ancestral biological history of the species. Why they should be increased by certain heterologous stimuli is also beyond present explanation.

Without going further into the diagnostic applications of antibody reactions, it should be said that in many infections, even where a serological test would be of the utmost value, specific antibodies cannot be demonstrated, or are present in such small amount as to render an antibody test impracticable. In tubercle and in gonorrhoea complement deviation tests with the patient's serum and cultures of the corresponding organism have been extensively applied, but their practical value is limited. Generally speaking, serological tests have had a restricted application in medicine, but where they have proved practicable the results have been of outstanding service in adding to diagnostic efficiency.

Apart from clinical diagnosis, immunity reactions have been extensively utilized in bacteriology for the identification of species. The system is the same as in the diagnostic tests, but in this case the antibody is the known quantity, the antigen the unknown. In short, certain species—for example *B. typhosus*—can only be accurately identified by testing the organism with a serum containing a specific antibody to this species, obtained by animal immunization. The agglutinin is the antibody almost entirely used in this work.

This application depends on the specificity of antibodies. While in certain cases antibodies are specific for the biological species, specificity may be more restricted and limited to what we call serological types within the species. The serological distinction of types (for example, among

pneumococci, meningococci) has exerted an important influence on artificial immunization. In the case of the pneumococcus three well defined types can be recognized, and, by immunizing animals with the separate types, an antiserum has been obtained to Type I which, given intravenously in large doses, is capable of reducing the mortality of cases of pneumonia due to this type.

I should like to state a general rule that applies to immunization and then instance exceptions of practical interest. Antibody immunity can only be produced by the introduction into the tissues of an alien or foreign antigen. Thus an animal cannot produce antibodies to the red cells of its own species or a *fortiori* its own cells.

In the condition known as paroxysmal haemoglobinuria, the result usually of syphilis, for some unexplained reason a specific substance of antibody nature is developed to the individual's own red corpuscles. This body is haemolytic (autolysin), and under certain conditions is capable of producing intravascular haemolysis and haemoglobinuria. Blackwater fever, a recognized complication of malaria, has also been regarded by some as due to a similar autolysin, but the evidence is inconclusive.

Red corpuscles are susceptible to agglutination by serum antibodies in the same way as bacteria. A haemagglutinin may be produced by immunizing in the usual manner with the red corpuscles from another species, but one of the most remarkable serological observations has been that the serum of certain individuals, for example, in the human species, may agglutinate the red cells of others, and that according to this mutual reaction of serum and cells, human individuals can be grouped into four well defined classes. This subject became prominent during the great war, when blood transfusion was a routine procedure, and when the injurious effects due to intravascular haemagglutination had to be avoided by ascertaining the effect of the recipient's serum on the donor's red cells. Here we have an instance of a serum substance, possibly of the nature of a natural antibody, acting on an antigen from the same species, and thus the agglutinin is spoken of as an isohaemagglutinin. It is of further interest that such group characters are hereditary and follow Mendel's law, and out of this has come a method by which, in certain cases, disputed paternity might be decided.

There are other interesting applications of antibody reactions to which I might refer, but the instances I have given are sufficient to show the ramifications of the subject and the practical results of its study.

#### NON-SPECIFIC IMMUNIZATION.

Perhaps one of our most difficult problems in applied immunity at the present time is that of "non-specific immunization," by which is meant the production of increased resistance by other than specific measures. The accumulated clinical evidence that an infection may be favourably influenced in this way cannot be ignored. For example, there is some reason to believe that the intravenous injection of certain proteins (for instance, proteose preparations, bacterial vaccines) is efficacious in cases of arthritis, including rheumatoid arthritis, and it might be argued that frequently the beneficial effects of vaccines are non-specific in nature.

The commonest method of non-specific therapy has been the intravenous injection of foreign toxic proteins, and the empiric aim is the production of what is called "protein shock." By this is meant a reaction to the foreign substance manifested clinically by rigor, fever (or, if pyrexia already exists, a further elevation of the temperature), aggravation of any local lesion, and various other symptoms associated with the fever. Along with these external effects there may be an increase in the nitrogen excretion indicating an effect on tissue metabolism, a "leucocyte stimulation" and increase of leucocytes in the circulating blood, an increase of proteolytic ferments in the serum, and possibly an increased output of antibodies. In short, the result might be regarded as a temporary exaggeration of the general reactive process which is the essential element in acquired resistance.

Apart from the parenteral injection of toxic proteins, other measures have been employed with a view to producing non-specific effects—for example, the artificial

abscess following the subcutaneous injection of turpentine, and even the artificial interposition of another infection. The fact that an intercurrent infection might influence an existing infection has long been recognized. It has even been suggested that counter-irritants, from the seton and cautery to the poultice and blister, owe their accredited effect to such non-specific action, and that irradiation by sunlight and other rays, the injection of colloidal metals, and certain drugs (iodides, for instance), act in the same way.

This form of therapy has now been extensively exploited, and the clinical data do not always supply the most convincing proofs. On the experimental side proof of non-specific immunization might be based on immunity reactions, or protection, experiments in animals. An apparently non-specific reaction demonstrable by antibody effects has been exemplified in persons vaccinated with typhoid vaccine and subsequently developing another infection at a time when the "post-vaccine" agglutinin have almost disappeared from the blood. The second infection leads to a renewed production of the typhoid agglutinin. Thus heterologous stimuli may increase the output of antibodies once the tissues have been sensitized by the specific stimulus. The reappearance of latent antibodies has also been demonstrated in animals as the result of injection of a heterologous bacterium or even non-bacterial proteins—that is, the types of substances used for non-specific therapy. The heterophil antibodies already referred to also exemplify non-specific immunization.

By protection experiments on animals it has been shown that increased resistance may be produced non-specifically. Thus Harvey and Iyengar found that in pigeons a relative immunity to *B. arisepicus* resulted from the injection of *B. coli* vaccine, though quantitatively inferior to that produced by a specific vaccine. In experiments of my own, evidence has been elicited that the resistance of guinea-pigs to experimental infection by *B. diphtheriae* could be increased by the injection of normal serum from various animals and even from other individuals of the same species, though also inferior to the protection conferred by a specific antitoxin.

Non-specific therapy, therefore, is not without some support on the laboratory side, and the further exploration of this field in the treatment of infective disease seems justified.

### HOW INTERFERENCE IN LABOUR MAY BE LESSENER BY EXAMINATION DURING PREGNANCY.

BY

JOHN S. FAIRBAIRN, B.M.Oxon., F.R.C.P.,  
F.R.C.S.,

OBSTETRIC PHYSICIAN, ST. THOMAS'S HOSPITAL, LONDON.

My purpose is to draw attention to the application of the methods of modern medicine to the particular problems of midwifery practice. These methods may be stated shortly as, first, the effort to maintain normal functioning by removing any known cause of its disturbance, and, secondly, detecting the earliest sign of disordered function with a view to immediate treatment and cure. If this is our attitude of mind towards the digestive, cardiac, and other functions it must equally be so in regard to the whole reproductive function, including that of parturition.

An anticipatory vision in the management of labour is the most striking development of this attitude of mind applied to the practice of obstetrics. Its relation to the old practice may be aptly compared to the difference between an army commander relying on his tactical skill in emergency to repel surprise attacks, and one who, with all modern means of discovering his enemies' intentions, breaks up threatening concentrations before the attacks mature. Indeed, the prematernity supervision may be termed the intelligence branch in the war against mortality and disability in childbirth.

Ante-natal supervision is as yet in its infancy, and much

\* Address delivered to a meeting of the Swansea Division of the British Medical Association.

still remains to be done to improve its methods of investigation. Some enthusiasts have run the new thing to death, and their methods have tended to make the pregnant mother consider her condition as pathological rather than physiological. This danger must be kept in mind and the purpose of the supervision and examination explained to the woman. So far as possible, investigation of suspected abnormalities should be made as little obvious as can be. The chief aims of the supervision may be stated as:

1. Maintaining health of body and mind in the pregnant woman.
2. Preserving the pregnancy to full time.
3. Foreseeing and avoiding preventable difficulties in labour.
4. Preparing the mother for the nursing and care of her child and generally educating her in regard to her own health and that of her family.

If these aims are successfully carried out their effect on maternal and infantile mortality and disability is too obvious to require mention. Reproduction, though physiological, puts a severe strain on the efficiency of every system of the body, and, like passing recruits for active service and "retting" the crews in a boat race, the thorough investigation of the state of health of the woman early in her pregnancy and further observation to see how she is standing the test, seem but reasonable precautions. Quite apart from those who have some organic weakness and who may break down under the strain, there are special illnesses, such as the toxæmias of pregnancy, that may arise, even in those in the best physical condition. Putting on one side the loss of prospective life, miscarriage is a prolific cause of operative interference during or after its occurrence, often as an emergency and in unfavourable surroundings, and of subsequent disability. Stillbirths and early infantile mortality for the most part result from toxic states of the mother (for example, syphilis and albuminuria), prematurity, and birth injuries. The good health of the mother throughout child-bearing means not only that her resistance to infection and disease is increased, but also her efficiency in looking after her family when they are most in need of her care.

Though the health of the mother will be the primary consideration throughout pregnancy, it will be noticed that there is a difference between the objective in the early and in the later months—say, after the viability of the foetus. In the first three months or so the preservation of the pregnancy is the chief matter; in the last two months the purpose of the investigation will chiefly be towards foreseeing and preventing difficulty and complications in labour.

The ante-natal supervision should be directed to the maintenance of the general health at its best and to the removal of all possible septic foci and the discomforts and troubles connected with the pregnancy; but it is impossible to go into so large a problem, and I will select two types for detailed consideration, as illustrative of the methods employed: first, the woman with albuminuria, and, secondly, the cases of possible difficulty in labour from malpresentation and misfit.

#### ALBUMINURIA.

In regard to the first, I do not wish it to be thought of solely in terms of eclamptic convulsions and possible complications in labour, for there is a far commoner possible result, and that is permanent renal damage. As the testing of the urine is the first sieve to strain out cases for further investigation, the next point is to determine the meaning of the albuminuria, and for that it is necessary that a catheter specimen should be obtained, so as to make sure that the albuminuria is not due to contamination after the urine has left the bladder; and then a further chemical and bacteriological examination may be necessary to exclude those cases due to pyelitis or cystitis—that is, those in which the albuminuria has arisen after excretion from the kidneys. The next point to determine is how far the renal function is affected, for albuminuria by itself is not proof positive of its disturbance. Diminished secretion, the presence of casts, oedema, and raised blood pressure would indicate renal damage, and to determine its degree the urea concentration test should be carried out. As soon as any impairment of renal function is discovered the essential matter is to keep the patient strictly to bed, and observe what rest with a restricted protein intake will do. In most cases the effect of the diminished metabolism is the rapid

recovery of the renal function and the disappearance of the albuminuria. In the more severe cases, however, improvement may be slow or may not occur. If, after a couple of weeks, no improvement results, and still more if the continuance of headache and sickness, increased oedema, and persistent high blood pressure show that the condition is both serious and resistant to treatment, the pregnancy must be terminated, for fear of progressive and permanent renal damage, or, more rarely, eclamptic convulsions. Improvement, even if slow, will justify further observation. One of the most obvious clinical signs for the termination of the pregnancy is a rising or persistently high blood pressure, as it is a warning of the onset of eclampsia. Dimness of vision with oedema of the retina and exudate is another indication for the immediate termination of the pregnancy, because of the risk of permanent damage to the eyesight. The same principle holds good in other disorders of pregnancy, and that is to determine how far conditions will yield to treatment, and, only in those cases in which other measures have failed, to resort to the induction of abortion or premature labour.

#### MALPRESENTATION AND DISPROPORTION.

I intend to confine my remarks this evening chiefly to the examination necessary to discover the position and presentation of the foetus, the pelvic capacity, and, so far as possible, to detect any factors likely to complicate the labour. This part of the examination is not begun till the last two months of pregnancy—that is, about the thirty-fourth week—as before then it is rarely possible to discover with accuracy the presentation, and, even if it were, a completely different state of affairs may be present a few weeks later. Before the thirty-fourth week induction of labour is rarely worth while, as the chances of survival of the child are too slender.

The general physical development of the woman should be noted, both in the erect position and when lying down. A height under 5 feet, narrowness across the hips, spinal curvature or other deformity, lameness due to disease of the hip-joint or to infantile palsy, should always suggest the need for special care. Bone or joint disease or other condition that has necessitated a long period of lying on the back during childhood may have checked the full development of the pelvic girdle. The appearance of the abdomen should be carefully observed, both when standing up and recumbent, and the size, shape, and position of the uterus noted. The pendulous abdomen of the multiparous woman is easily recognized and is especially marked when standing up; it is liable to be accompanied by late engagement of the head and malpresentation, and requires support during the later months of pregnancy. The history of the previous labours may indicate whether there has been difficulty before, but even if there has been none it must not be forgotten that the deviation of the uterine axis may cause malpresentation at the beginning of labour, thus calling for careful observation as soon as labour has started, and that other factors may be present that were not previously. In a first pregnancy, on the other hand, unusual forward projection of the uterus, especially if persistent even in the dorsal position, indicates deficient space in the abdominal or pelvic cavity. The common causes are overdistension of the uterus, small abdominal capacity, as in short stumpy women or those with spinal deformity (for example, kyphosis), bringing the ribs close down to the iliac crest, or pelvic contraction preventing the descent of the head into the pelvis so that the foetus is entirely abdominal. Decided forward projection of the uterus in a first pregnancy should always attract attention, but the cause is usually readily determined, and all cases in which it is due to non-descent of the presenting part should raise the suspicion of some misfit between the head and pelvis.

The diagnosis of presentation and position is carried out by the ordinary obstetrical examination, and should be confirmed again later. Rectification of a breech presentation is most easily effected about three weeks before term, and though rectification of the foetal lie and the uterine obliquity by padding and a binder may be tried in shoulder presentations, the more favourable time, owing to the tendency to recurrence, is as a rule at the commencement of labour. In any case in which external version has been

done further examination is necessary to see that there has not been a reversion to the original presentation. Face and brow presentations are rarely recognized at the ante-natal examination, and, if recognized, are not readily converted to, or maintained as, a vertex. For the most part they arise at the onset of labour, and, as in oblique lies, reliance must chiefly be placed on discovering the high position of the head and the conditions liable to give rise to them, and trust to rectification at the onset of labour. Occipito-posterior positions are likewise best treated either just before or immediately at the onset of labour by a pad and binder, after the method of Buist.

The other important part of the obstetrical examination is that of the pelvic capacity, which is carried out by two different methods—one pelvimetry, and the other the estimation of the fit of the head into the brim. The two methods are complementary, and although formerly the measurements were thought to be all-important, wider experience has led to their being looked upon rather as a rough guide and so relegated to a secondary place, the fit of the head in the brim being taken as the deciding factor in determining treatment.

The abdominal examination is especially important as the simplest method of picking out those cases requiring further investigation. The head high up and floating above the brim is easily accessible to palpation. If it has descended into the pelvic cavity the fingers must be sunk into the pelvis in order to recognize the hard and immovable mass filling up the sacral hollow. A high position of the head in a primigravida during the later weeks of pregnancy must always be taken as a warning of possible trouble. The head is commonly found in the cavity during the last month or six weeks of pregnancy, and a high position in the last two weeks must always call for full investigation. In multiparæ, especially those with a lax abdominal wall, there is neither the same tension within the abdomen to drive the head downwards nor does the uterine axis lie directly in that of the inlet to facilitate descent, and hence a high position of the head has not the same significance. The history of previous labours in these cases, however, will generally serve to decide whether there is a diminished pelvic capacity, but the possibility of undue size of the head must be borne in mind.

A rough test can be made of the relation between the size of the head and pelvis by pressing the head downwards from the abdomen. If the two poles of the head, the forehead and hind-head, can be felt very distinctly a transverse position of the head with some degree of extension is probable, indicating some flattening of the brim. If in addition the biparietal prominence is easily recognizable, and still more if on pressing down the head it bulges over the pubes, there is definite evidence of misfit. Willett emphasizes the important evidence that can be obtained by laying the flat of one hand on the suprapubic region while the head is pressed down between the fingers and thumb of the other hand, when the parietal eminence, if felt, must be taken as a warning during pregnancy and a danger signal in labour. He also holds that if the palm of the hand is placed on the parietal eminence, it may be found that when the patient sits up and leans forward the parietal eminence sinks below the pubes, showing that the head will pass the brim. By pressing the head into the brim with the patient in the dorsal position an impression can thus be obtained of the amount of room and of the ease with which the head will enter, and those cases in which difficulty is suspected should then be reserved for further examination by the bimanual method. The treatment of the minor degrees of misfit between the head and the pelvis is by the induction of labour before the child is large enough to cause difficulty, and yet not too small to give trouble in rearing.

The cases of high position of the head with difficulty in making it enter the pelvis, picked out by the rough abdominal examination, are now examined bimanually—that is, with two fingers of one hand in the vagina, whilst the other hand on the abdomen presses the head down into the pelvic cavity. This method is more accurate because the internal fingers can be placed fairly accurately in the centre of the pelvis and the pressure of the head directed on to

them—that is, nearly in the proper axis—thus obviating a difficulty in the abdominal method, where pressure is liable to be made either too much backwards on to the sacral promontory or too much forwards on to the pubes. The fingers in the vagina also estimate the degree of descent of the head, how far it can be made to slide down behind the symphysis, and how tightly it fills the inlet and cavity, or whether it merely sits on the brim and bulges over the pubes. As soon as the bimanual examination shows a tight fit, the examination is repeated under anaesthesia and the final decision made as to whether to proceed at once to induction or postpone it for a week or two.

If the patient is examined at the thirty-fourth week, and it is then discovered that disparity between the head and the pelvis is such that even at this early stage natural delivery is unlikely owing to a serious degree of pelvic deformity, Caesarean section at term would be selected. These cases are, however, very rare, and in the lesser degrees of deformity the woman would be seen every fortnight. The fit of the head would be judged by rough estimation until difficulty in pressing down the head was detected, when the bimanual examination under anaesthesia would be made in order to decide the most suitable time to induce. Except in the extreme degrees of pelvic deformity, in which delivery of a living child by the natural passages is clearly impossible, the tendency will be to prefer induction in a young woman so as to have accurate knowledge of what is possible by the natural powers. Nothing is learnt from Caesarean section, and the scars in the uterus and abdominal wall are a source of weakness and a cause of anxiety in all future pregnancies and labours. For a time the more dramatic Caesarean section was overdone, largely because a short-sighted view, limited to the one pregnancy, was taken instead of a wide vision over the future reproductive life of the woman. In a young woman with the whole of her reproductive life in front of her an early induction should be preferred, even if it offers but a slender chance of the child being reared. A natural labour carefully observed and conducted will teach us much more than we can learn from the most thorough examination, and in a young woman with twenty years of reproductive life in front of her it is much better for her future to make a trial trip of her first pregnancy and know by experience what the natural powers can do. Usually they will do better than we expect. On the other hand, in a woman who has had previous labours in which induction has failed to give a living child, or in a woman in her first pregnancy towards the end of her reproductive life, Caesarean section would clearly be the preferable method of delivery, as securing her a living child in what might be her only pregnancy.

#### OTHER CAUSES OF INTERFERENCE.

These examples will suffice to indicate how complications in childbirth from malpresentation and misfit may be eliminated by anticipation, investigation, and treatment during pregnancy. There remain, however, the haemorrhages and convulsions, to which passing reference must be made, as both are considerable items in making up the mortality in child-bearing. We know so little as to the causation of ante-partum haemorrhage that our endeavour must be to take the first occurrence of bleeding as a warning of possible further trouble to come. Except that accidental haemorrhage occurs more frequently in women suffering from albuminuria and the intoxications of pregnancy, we know nothing of the causes of separation or abnormal implantation of the placenta. As the causes are unknown, the second best must be done by considering the occurrence of any bleeding of moment as a warning of the possibility of more serious trouble ahead, and therefore keeping the patient at rest and under observation and being prepared to take immediate action if the need arises. If placenta praevia can be definitely diagnosed, it is unsafe to temporize. Eclamptic convulsions rarely occur without albuminuria or other warning signs, and thus their unexpected onset is greatly limited by proper ante-natal supervision; they may, however, occur occasionally in patients under observation and treatment for albuminuria, when they are not usually serious, or may develop suddenly with little warning.

I have tried to show how far the complications due to malpresentations and misfits, to ante-partum haemorrhage and convulsions, with consequent interference in labour, may be greatly lessened. Errors due to miscalculations will be with us so long as we remain erring mortals, but as we become more experienced they will become fewer. There will, however, be left over four-fifths of the interference in labour—the low forceps delivery, the “shoe-horn” operation of easing the head over the perineum because of failure of the forces of labour to overcome the final obstacle of the resistance of the levator ani muscles. Happily this procedure is a minor one, but even it calls for a fresh attitude of mind in regard to it, though that is another story which I cannot begin to-night. The forceps must be regarded as our second line of defence after our first line has given way, and we must try to strengthen the first line, which is to seek out the causes of the ineffectiveness of the powers and remove them—of which fatigue, long-continued pain, anxiety, and dread of the ordeal are the most prominent.

## Lectures

OR

# THE SYMPATHETIC INNERVATION OF STRIATED MUSCLE.\*

BY

THE LATE JOHN IRVINE HUNTER, M.D., Ch.M.,  
CHALLIS PROFESSOR OF ANATOMY IN THE UNIVERSITY OF SYDNEY.

## LECTURE II.—PART II.

### THE FUNCTIONS OF THE TWO GROUPS OF MUSCLE FIBRES:

#### EXPERIMENTAL EVIDENCE (Continued).

#### EXPERIMENTS ON BIRDS.

THE folded attitude of the wings of birds when standing or walking affords an excellent example of what Sherrington has called an “active posture”—namely, the maintenance of position against the action of gravity by means of the activity of contractile tissues. I thought a study of the mechanism concerned in the production and maintenance of this posture would throw light on the postural activity of voluntary muscle generally, and provide a means of determining the exact part played by the dual nerve supply—somatic and sympathetic—of such muscle in the production and maintenance of posture.

The effect of gravity, which would be freely acting under normal conditions in some birds, would tend to cause drooping and falling outwards of one wing, if the mechanism for the maintenance of its posture were interfered with, and by comparison with the position of the normal wing of the opposite side the degree of interference is readily measurable. The wing offers advantages for study over the limbs of the cat, dog, and goat, in which the normal attitude is extension, for compensatory efforts are necessary in order to retain this position in the interests of maintaining the erect attitude. This tends to mask the effects of injury reducing the efficiency of the postural mechanism. Variations in the position of the wing may also be studied more easily than alterations in the degrees of flexion of the hind limbs of the frog after sympathetic ramisection, as suspension of the frog (which is necessary to allow the normal side and the injured side to be compared) introduces rotatory reflexes. This circumstance renders a careful analysis necessary in order to dissociate the effects of labyrinthine impulses from the proprioceptive effects produced in the musculature of the limb itself (cf. Langelaan, *Brain*, 1915 and 1922).

In his memoir, “The Postural Activity of Muscles and Nerve,” Sherrington says:

“Section of the afferent roots of the wing affects little, if at all, the folded posture maintained by the wing when not in flight, i.e., during standing or walking. Nor has the source of the postural

contraction of the flexors of the wing been found. Here, as in the case of the iris, the postural contraction, if, as is presumable, reflex, lies in receptors not those of the contracting muscle themselves—is, in short, *allogeneus* not *autogeneus*.”

In view of our experiments on goats it appeared to me that a possible explanation for the failure to alter materially the folded position of the wing, by severing the posterior nerve roots corresponding to the origin of the brachial plexus, was due to the fact that in such an experiment the sympathetic innervation of the voluntary muscle of the wing was left intact. In previous papers (see, for example, *Surgery, Gynecology and Obstetrics*, December, 1924) I have argued that the function of the sympathetic nerve supply of skeletal muscle is the maintenance of posture once the position is attained—in other words, that it is responsible for the property of plastic tone. It appeared desirable, therefore, to ascertain the effect of removal of the influence of the sympathetic nerve supply of the muscle of the wing by section of the cervical sympathetic. The result of the first experiment of this kind has already been recorded.<sup>12</sup> The wing was markedly drooped compared with the normal side when the body of the fowl was supported in the hand during recovery from the anaesthetic. Later the droop of this wing was definitely noticeable but not so marked, its tip being 1.5 cm. lower than the tip of the intact wing. The wing also was less firmly folded to the side of the body. This condition was still noticeable when the fowl was kept at rest for some minutes up to the time of being killed seventy-four days later. A *post-mortem* examination revealed that the vertebral sympathetic cord had been cut below (or behind) the upper two roots of the brachial plexus only, so that the effect was incomplete. Subsequent operations of a more complete character, in which the sympathetic was approached by dissection of the intertransverse spaces from behind, instead of from the front as in the first experiment, gave similar results.

#### Anatomical Features of the Cervical Sympathetic Trunk of Birds.

The vertebral sympathetic plexus or cord, which contains the fibres that interest us in these experiments, passes through the foramina of the transverse processes along the vertebral vessels on a plane ventral to the roots of the brachial plexus. On approaching the ribs the cord usually

splits into dorsal and ventral trunks, which pass respectively dorsal and ventral to the neck of the rib. The operation usually performed on the fowls was to divide these trunks above the first true rib (at C in Fig. 7)—that is, caudal to the last large nerve (the last cervical) which contributes towards the formation of the brachial plexus. In sea-gulls I invariably cut the dorsal and ventral trunks immediately behind (or below) the penultimate cervical nerve as well. This section produced a more

FIG. 7.—Diagram of the fowl's brachial plexus. C, The spot where the whole sympathetic connexions of the wing can be severed. D, The line along which either the posterior or the anterior somatic roots or both can be cut.

marked effect on the eyelids than the more caudal section. Langley has shown that the last cervical nerve is the first nerve through which pre-ganglionic fibres of the sympathetic nervous system emerge from the spinal cord. He records that the criterion of movement of the feathers following stimulation shows that these fibres are distributed to the upper part of the neck and the head. It may be distributed to the anterior part of the wing, but the effect is only slight when it occurs there. Therefore the more caudal section of the sympathetic

\* Delivered by Professor Elliot Smith at University College, January 25th, 1925.

chain satisfies the purpose of the present investigation. But the changes in the position of the eyelid are useful as indications that the chain has been successfully identified and cut. In the fowl the effect of section of the cervical sympathetic above the last cervical nerve (at C in Fig. 7) produces a raising of the lower eyelid and a more marked drooping and overhanging of the upper lid, so that the pupil is partially obscured. Normally the upper lid is retracted to such an extent that only its free edge is visible. After the operation, especially when viewed from above, it may be seen for an extent of several millimetres. When the effect is not so apparent as in the lower section alone a useful test is to draw the upper lid down over the eye on each side and compare the rate of its return on the two sides. It returns perceptibly more slowly on the operated side, and the return is, of course, not complete. The effects on the eyelid of the sea-gull are not so noticeable as in the fowl because they are smaller and less mobile. But the circular palpebral tissue becomes oval in shape following the operation.

The removal of the cervical sympathetic cord has an effect upon the pupil in the bird, as Langley has shown. The test of ruffling the feathers described by Langley is useful to determine whether the operation has been successful. On the normal side the feathers rapidly return to their normal depressed condition, whereas on the side from which the sympathetic innervation has been removed the return is slow.

In this series of experiments the effect upon the blood vessels was not used as a criterion to indicate whether the sympathetic had been severed or not. In one case a marked increase of temperature of the comb occurred on the side of the operation. In another marked pallor was observed in the vascular appendages of the head following the operation. This was probably due to a state of strong contraction of the capillaries following sympathetic denervation described by Krogh. On examination on the following day in the above instance it was again present.

#### *The Effect of Section of the Cervical Sympathetic upon the Posture of the Wing.*

The immediate effects upon the position of the wing of section of the cervical sympathetic cord have already been briefly noted. In the fowl the wing is somewhat drooped on the affected side. This persists after healing has completely occurred. For instance, in one of the fowls the distance of the tip of the wing from the mid-line, as measured by the callipers on the eleventh day following the operation on the left side, was 4.2 cm. on this side, compared with the corresponding measurement of 3 cm. on the normal side. When the wings were stretched outwards and then simultaneously released, an average of three measurements on the left and right sides were 4.2 cm. and 2.2 cm. respectively. These differences are in part due to the falling away of the limb from the side (abduction) in addition to dropping downwards. An estimate of the difference due to these causes is also obtainable by measuring the distance of the outer surface of the wing at the level of the elbow-joint from the mid-line on each side. On the day in question the left and right measurements were 10.1 cm. and 8 cm. respectively.

Another change due to the operation is the slowness in the return of the partially denervated limb to its final position when released after stretching outward or downward or after elevation. This effect is perceptible to the eye and is constant over numerous trials. Cinematographic records confirmed this observation. The greater part of the return movement takes place relatively rapidly, though not so rapidly as on the normal side. The limb remains somewhat abducted and elevated, and then slowly settles down to its final position, which is closer to the trunk and in a somewhat more depressed position. This latter element in the return movement may occupy several seconds. If the wing is passively placed in its normal position it rapidly falls to the depressed level. Sometimes the bird itself voluntarily lifts the wing to its normal position, but it quickly falls to its original position. This effect becomes more marked in fatigue—for example, after repeated examination.

In sea-gulls abduction and dropping of the elbow is apparent, but the effect is not so marked as in the fowl, because the tail is normally used to support the large wings, which in some of the specimens operated upon attain a span of a metre from tip to tip. In the normal position of the wings they lie crossed over one another resting on the tail. Subsequent to cervical sympathetic section the affected wing takes a position nearly parallel with the direction of the tail, and, following a two-sided operation, an interval may exist between the two wings which is not normally to be seen. When an affected wing is removed from the support of the tail it droops below the tail level approximately to the extent of 2.5 cm. The drooping of the wing is very marked during the process of recovery of the limb from the anaesthetic. Open ether was the anaesthetic employed in each experiment.

For purposes of control the vertebro-scapular muscles were severed on both sides, and both right and left sympathetic cords were exposed, but only the left was cut. The only difference between the two sides, therefore, is that section of the sympathetic cord was performed on the left side and not on the right side.

It is apparent from these remarks that the tone of the affected wing is reduced so that the normal posture is not perfectly maintained. But considerable tone remains, and it tends to impose a folded posture upon the wing. This influence must be due to the presence of the somatic proprioceptive reflex arcs which remain intact, but in the absence of the influence of the sympathetic innervation of the wing the maximum position of abduction and flexion can no longer be maintained against the action of gravity. This force leads to some degree of drooping and abduction of the wing. During light anaesthesia the effect is rendered more evident as the result of the partial removal of the influence of the somatic proprioceptive connexions. The influence of the somatic arcs is also markedly reduced by fatigue, as already noticed following repeated stretching of the wing in the fowl. The natural effort of sustaining flight shows the result of fatigue to greater advantage. These observations were carried out with the bird attached to a light line mounted on a smoothly running reel. In the unilateral operation the position of the normal wing may be used as a control, as in sea-gull 3. Before flight only slight abduction and droop of the elbow region of the wing were apparent. After a flight of one hundred metres, in which the wings were maintained in constant movement so that no gliding occurred, the abduction and drooping became very marked. The wing no longer rested on the tail, and the bird made ineffectual attempts to place it in its usual position. On supporting the body of the bird in the hand and allowing the wings to drop freely a condition resembling that seen in similar circumstances during recovery from the anaesthetic resulted. Fatigue of the somatically innervated muscles has apparently produced this effect, so that the condition of the wing in such circumstances is not far removed from that seen in flaccid paralysis.

These observations are in accord with the results of our operations on goats—namely, that the sympathetic innervation of voluntary muscles is responsible for the maintenance of plastic tone. The defect following removal of the sympathetic influence consists in inability of the voluntary muscle to remain fixed at a given length—such, for instance, as the length required to maintain the extended position of the limbs in a quadruped when placed on its back, the flexed position of the frog's hind limbs, or the folded position of the wing normally assumed when a bird is walking or standing. The flexed posture of the wing, to take the latter instance, is conferred upon the wing by the intact somatic proprioceptive reflex arc; and this tendency disappears when this arc is interrupted. Therefore this arc, when intact, subserves contractile tone (Langelaan, 1922). The position of flexion of the wing imposed by the contractile fibres fails to be maintained to the full degree in the absence of plastic tone, which is subserved by the sympathetically innervated fibres of the striated muscle of the wing. Normally, therefore, plastic tone is the property of muscle enabling the flexed position to be maintained. The "catch" or "ratchet" mechanism of involuntary muscle described by Uexküll is beautifully illustrated. The fixed

position of flexion of the wing can no longer be maintained for an indefinite period with a minimum of fatigue in the absence of the sympathetic arc. Furthermore, after voluntary activity of such partially denervated muscle, of which flight provides the best example, exhaustion of the somatic reflex mechanism manifests itself to a striking degree. It is evident, therefore, that the sympathetic innervation plays a part in movement as well as at rest. To retain the analogy already mentioned, it would appear that an "infinitely fine ratchet" assists in voluntary movement. This helps to maintain the intermediate postures through which the muscle passes during the execution of an active movement.

In the absence of the sympathetic nerve supply it is apparent that greater work is imposed upon the somatic nervous system during voluntary activity, for it not only performs the voluntary movement, but alone supports the weight of the limb. When both wings have been partially denervated by removal of the sympathetic nerve supply (as in sea-gull 8) after several short flights both wings were drooped and the bird was apparently exhausted, the mouth was widely open, and respiration very rapid. On being approached the bird only attempted short low flights to avoid recapture.

The effect of the section of the cervical sympathetic trunk in narrowing the palpebral fissure is to be ascribed to loss of plastic tone of the striated muscle of the eyelid to a greater degree than to the denervation of involuntary muscle. Dr. Oliver Latham of Sydney has made gold chloride preparations which show the sympathetic non-medullated fibres terminating in characteristic grape-like endings on considerable bundles of the eyelids. Removal of the influence of these fibres affects the capability of the muscle to remain fixed at the length required to maintain the eyelids widely separated.

#### *Section of the Afferent Limb of the Sympathetic Proprioceptive Reflex Arc.*

By cutting the posterior nerve roots (see the line D in Fig. 7) Sherrington conclusively proved that tone is subserved by a proprioceptive reflex mechanism. The question arises, then, as to whether a sympathetic proprioceptive reflex arc is responsible for the production and maintenance of plastic tone. Langley showed that the feathers of the wing are influenced by stimulation of the last cervical nerve and the upper two thoracic nerves. Of these the first thoracic nerve has a strong effect on the wing. The anterior part of the wing may be affected by the last cervical nerve, but this effect when present is only slight. The second thoracic nerve has a moderate or slight effect, usually on the posterior part of the wing only. Acting on the supposition that the sympathetic innervation of the voluntary muscle of the wing would have the same origin as that of the feathers, an operation was performed on the first thoracic posterior nerve root. This may be done by enlarging the first foramen seen on the dorsal view of the fused thoracic vertebrae. Post-mortem examination showed that this root was completely severed without injury to the anterior nerve root. In this case the brachial plexus received no somatic contributions from the first thoracic nerve. The large size of this root in all the specimens operated on is a striking feature in view of the slight part, if any, this segment takes in the formation of the brachial plexus. This confirms the suggestion that this nerve contributes the principal sympathetic connexions to the wing, so accounting for its large size. The effect of removal of the posterior root of this nerve upon the posture of the wing is in all respects the same as that following section of the cervical sympathetic cord caudal to the brachial plexus. Drooping and abduction of the wing are apparent; and, on releasing the wings after stretching, the affected side was perceptibly slower in returning to its final position. On the fifth day the measurements were as follows: The tip of the wing was 2.5 cm. from the mid-line on the left side, and 0 cm. on the right side; or, measured by the callipers, the elbows were 80 cm. and 6.8 cm. from the mid-line respectively. When the wings were stretched outward and then released the tips were 2.7 cm. and 2 cm. from the mid-line on the left

and right sides respectively. It is evident, therefore, that if a sympathetic proprioceptive arc subserves plastic tone afferent fibres must descend along the ganglionated (vertebral) chain to the first thoracic level and there pass to the nerve trunk at this level by way of one or other or both rami communicantes. In the experiment of section of the cervical sympathetic posterior to the brachial plexus both afferent and efferent fibres are therefore severed. The same effect follows section of the afferent limb of the arc only when the first thoracic posterior nerve root is cut through. Sherrington's preparations, in which the afferent nerves were cut, owe some of their features to removal of the influence of the sympathetic proprioceptive reflex arc subserving plastic tone, for in "deafferenting" the fore limb of the cat he removed *inter alia* the posterior nerve root of the first thoracic nerve, and in the case of the hind limb of that animal the fourth lumbar posterior nerve root was one of the two roots resected. In the cat thoracic-lumbar outflow extends from the first thoracic to the fourth lumbar segment: hence Sherrington's operations included the region of the sympathetic innervation of the limbs.

#### *Persistence of Plastic Tonus after Removal of all the Posterior Nerve Roots Connected with the Brachial Plexus.*

The anatomical connexions of the somatic and sympathetic nervous systems and the wing musculature it is possible to remove the influence of the former materially affecting the innervation derived from the source; for the most important sympathetic connexion consists of a reflex arc at the first thoracic level. On one of the posterior nerve roots of four segments above this level were removed with a view to removing the influence of the somatic reflex arcs. In addition to the absence of voluntary movement the result of this operation is to remove the tendency of the wing to take up a flexed position—that is, contractile tone is absent. When the wing is stretched outwards, therefore, and released, it drops to the side of the bird, and instead of taking up the flexed attitude characteristic of the normal wing it remains dependent. If the wing is passively flexed it will remain in this new position. In this way the wing may be moulded into the position normally occupied by it, and it will remain there indefinitely.

The wing may now be drawn down to a dependent position, where it will remain. It has, therefore, the properties of a plastic body, enabling it to retain any position in which it may be placed. In other words, the flexors of the wing exhibit the "shortening and lengthening reactions." These reactions indicate the presence of plastic tone.

It may be inferred, therefore, that contractile tone, which normally tends to impose the typical posture upon the wing, is absent in such a preparation, and is therefore a function of the somatic proprioceptive reflex arc that has been destroyed. Plastic tone, which fixes the length of the muscle fibres to maintain a posture once assumed, is a function of the sympathetic proprioceptive reflex arc that remains intact. Together these components of tone are responsible for posture, so that the combination of the two may be called "postural tone."

In one fowl in which the posterior roots of the brachial plexus had been severed, the relationship between plastic tone and the sympathetic innervation of the wing musculature was shown by a further experiment. The cervical sympathetic was severed immediately below (or behind) the last cervical nerve, directly after an examination that revealed the presence of plastic tone in the wing. After the operation the plastic tone had disappeared. The wing was heavy and dependent as in flaccid paralysis. It would not remain in any position of flexion in which it was placed. When folded over the back of the bird it dropped heavily to the ground. This experiment proves conclusively that the plastic tone exhibited after the first operation was maintained by the sympathetic proprioceptive reflex connexions of the wing musculature. As other experiments have shown, this is at the level of the first thoracic segment in the fowl.

### Compensatory Increase in Contractile Tone after Sympathetic Denervation of the Skeletal Muscle of the Wing.

To test the duration of the effect upon the wing of severing the cervical sympathetic trunk caudal to the brachial plexus, the position of the normal and affected wings of some preparations were daily measured. I am indebted to Mr. R. E. Murray, who carried out these daily observations. Fig. 8 is a graphic record of these observations. One observation was made each day on the position of the elbow. An average of three readings of the position of the tips of the wings from the median line was recorded daily. Both graphs show the same features. The contractile tone increases in the affected wing until both wings are approximately equidistant from the median line. This condition is gradually attained and the distances become equal in about sixty days. A similar result is found after removal of the afferent limb of the sympathetic proprioceptive reflex arc.

When this compensation has taken place the effect of cutting the cervical sympathetic is manifested under two conditions; when the bird is kept at rest for a period of approximately fifteen minutes or longer, the droop and abduction of the operated side reappear. Fatigue has a

similar effect. Starting with the elbows and tips of the two wings equidistant from the median line, the left wing and then the right wing were each folded across the back by passive movement fifty times. The difference in the distance of the elbows from the mid-line was then 2.2 cm. and the difference in the distance of the tips from this line was 2.9 cm., due to the droop of the wing on the operated side.

Plastic tone was therefore still absent. It remains to account for the increase in contractile tone. Magnus and de Kleijn have demonstrated that pathways other than the afferent nerves from the muscles themselves affect the tone of skeletal muscle. These accessory influences are the labyrinths and the proprioceptors of the neck muscles. In the resting conditions both these sources of impulses would no longer be effective, and consequently the contractile tone would be lessened, as in the experiment recorded above. It is noteworthy that Langelan has shown that in frogs removal of

plastic tone from the hind limb leads to domination of the labyrinth of the opposite side. This leads to extension of the normal limb and increased flexion of the limb upon the operated side.

## THE HYPOTONIC (FLABBY) CHILD.

BY

DONALD PATERSON, M.B., M.R.C.P.,

PHYSICIAN FOR DISEASES OF CHILDREN, WESTMINSTER HOSPITAL;  
 PHYSICIAN TO OUT-PATIENTS, HOSPITAL FOR SICK CHILDREN,  
 GREAT ORMOND STREET; PHYSICIAN TO THE INFANTS  
 HOSPITAL, WESTMINSTER.

A CONSIDERABLE proportion of the children seen at the out-patient department of a children's hospital present such indefinite symptoms but such a uniform clinical picture that they were thought to be worth investigating in detail. These children are generally between the ages of 2 and 7 years, and are brought to hospital for such complaints as tiredness, lack of energy, pains in the limbs on continued exercise, knock-knee, flat-feet, or turning in of the toes when walking, and hence may be seen by either the general physician or the orthopaedic surgeon. Sometimes, however, the complaint was merely that the child had no appetite or was pale, and the usual diagnosis was "debility."

On examination of these children the most striking feature is their stance and their extreme lack of muscle tone. This is well shown in the figures. The large "pot" belly with compensating lordosis is the result of the extremely feeble development of the abdominal muscles. Hyper-extensible joints, knock-knee, flat-feet, turned-in toes, and winged scapulae are further expressions of this same lack of tone. The great majority of cases appear well nourished, but the limb muscles are so soft that it is sometimes difficult to judge whether they are really properly developed. It is interesting to note here that the calf and thigh muscles are always better

developed and have better tone than the arm muscles. Many have enlarged tonsils and adenoids, and some have a more generalized lymphoid enlargement.

Cameron<sup>1</sup> recently described a type of case frequently seen at the out-patient departments, which he terms the nervous child. This is not, however, the type of patient which the writer is attempting to describe and elucidate. The child which Cameron describes is as a rule an only child or the youngest child of elderly parents. He is thin, dislikes to hold himself in the upright position, and has what is described in America as the "fatigue" stance. His day is spent in bursts of activity and periods of collapse. During a period of exhaustion his stance is like those under investigation, but his muscles never at any time show the hypotonia of a flabby child. The metabolism of the "nervous exhaustion" child is as a rule overactive, and what is required for him is mental and physical rest.

With the hope of elucidating the etiology of this clinical syndrome of flabbiness an investigation of a large number of cases was undertaken during the past year at the Hospital for Sick Children, Great Ormond Street. Early in the investigation it was clear that a number of factors were involved, and the following is a review of these factors and of the various theories that have been put forward to account for the condition.

DIET.  
 Recently Mellanby<sup>2</sup> has stated that by diet alone in dogs he can produce every degree of muscular weakness and wasting and can cure the same by restriction of cereals and

addition of cod-liver oil. He also claims that the muscular flabbiness of rickets can be cured by the same line of treatment. He believes that the cereals have a neutralizing action on the antirachitic factor, so that on high cereal diets the dose of cod-liver oil must be increased. Vining<sup>2</sup> also believes in a dietetic error, probably carbohydrate excess, as one of the causes of the "debilitated state," although he considers the toxic factor to be more important.

An investigation was made of the diets of the children attending the out-patient department, and it was found that as a general rule they were all on the same badly balanced diet, which was too liberal in calories for the output of energy in the day. This diet was ridiculously high in carbohydrate, which was mainly cereal, and low in animal proteins and fats. Although all the children of the poor were on this badly balanced diet they did not all show flabbiness, and some had remarkably good tone. This difference was seen to occur even in the same family. Further, many of these flabby children were treated for months on therapeutic doses of cod-liver oil with no improvement, but at the same time it must be noted that the cereals were not restricted, as such a measure was impracticable when dealing with the out-patient class of patients. It is obvious from the above that other factors besides diet must be concerned in the production of muscular hypotonia.

It is interesting in this connexion to note the reports of Holt and Fales<sup>4</sup> on children in an institution in New York. These children received a most liberal diet, but one which included a large excess of carbohydrate (over 60 per cent.), and yet they were in most excellent physical condition. Practically the same portion of food was allowed to both the younger and older children, but both increased normally in weight and remained in good health.

#### CONFINEMENT AND LACK OF EXERCISE.

That rickets, and especially lack of muscle tone, is due to confinement has been the opinion of the Glasgow school for many years. Recently Galbraith<sup>5</sup> stated that although cod-liver oil caused a deposition of calcium in the bones and healed bony manifestations of rickets, nevertheless the muscular flabbiness remained as marked as ever. He reports rapid cures of flabbiness with massage and exercise.

That actual immobility does not necessarily produce lack of muscle tone is suggested by a study of the results of the open-air treatment of children suffering from tuberculous hips or spines, gross rickets, or congenital malformations. These children during their treatment are confined in splints for long periods, but they are lightly clad and exposed to both moving fresh air and sunshine, and under these conditions retain excellent muscle tone. This can be explained by the work of Leonard Hill<sup>6</sup> as due to the stimulating effects of sunshine and moving fresh air on metabolism. It is a matter of common observation that normal children with good tone who are confined to bed as a result of some acute illness rapidly become flabby, but after being up soon evince a desire to move about and quickly recover their muscle tone. This is in marked contrast with the true flabby child, who shows no desire for exercise. Undue confinement sometimes occurs even in the homes of the well-to-do, and though the children are taken out of doors they may not get sufficient walking exercise, as they are sometimes kept too much in their perambulators. At the same time these children are receiving an over-liberal diet and are excessively warmly clad.

Inquiries into the histories of the hospital cases showed that many of these flabby children had practically no exercise during the day, only being taken out for about one hour in the morning. The majority were confined to small quarters which were badly lit and badly ventilated. When the children reach the age of 4 or 5 years they are allowed out by themselves and also commence school; at this age the number of hypotonic children rapidly decreases. The superior tone of the calf muscles as compared to the arm muscles also becomes very remarkable at this age, although the same contrast to a lesser degree is seen in the younger children. This is obviously due to the fact that the calf muscles are those most exercised. Another interesting point noted was the frequent complaint that the children were always tired and slept much during the day.

From the above facts it would appear that lack of exercise and confinement, though very important factors in the production of hypotonia, will not by themselves produce flabbiness but must be correlated with others in order to have this effect.

#### TOXIC THEORY.

Vining<sup>2</sup> has suggested that toxic absorption from either the throat or bowel plays a most important part in the production of the debilitated state. Wills and Warwick<sup>4</sup> showed that children with septic tonsils as a rule had excellent muscle tone, but that true hypertrophy of the adenoid tissue of the throat was associated with flabbiness of the muscles. There is no evidence that toxic absorption is taking place from the bowel. The constipation which is present in a number of the cases is rather the result of the atonicity of the abdominal and bowel wall muscles than the cause of this condition. Against the toxic theory is the fact that in tuberculosis, syphilis, and rheumatism, all of which are chronic toxæmias, flabbiness may occur but is certainly not characteristic.

#### CONSTITUTIONAL DEFECT.

The theory is put forward by Czerny<sup>7</sup> that there is a type of child who is born with a particular constitution which he calls the "exudative diathesis." In this type the muscles are flabby, the child is inactive, shows general enlargement of the lymph glands, and is prone to infections of the mucous membranes. Whether such a child exists or not it is difficult to say. Certainly every clinician knows that there are infants who from birth are firm, quick in their movements, inclined to be under weight, and difficult to fatten, while other infants are slow in their movements, flabby, sleep a great deal, gain weight easily, and do this on a low caloric intake. In the former the metabolic fires are burning rapidly, while in the latter these fires are burning slowly.

#### CONCLUSIONS.

1. A consideration of the first two theories—namely, diet and lack of exercise—suggests that factors which tend to depress metabolism produce flabbiness, while factors which tend to stimulate metabolism cure flabbiness.

2. The factors which tend to depress metabolism and produce flabbiness are confinement, and lack of exercise, fresh air, and sunshine; overclothing with consequent heat retention, overfeeding or over-calorying in relation to the child's output of energy in the day; feeding with a diet too high in cereals, too low in animal fat and protein, and defective in vitamins.

3. The factors which tend to stimulate metabolism, and therefore cure flabbiness, are the reduction of the diet and especially of the cereals, retaining in the diet a sufficient amount of animal fat and protein; the administration of cod-liver oil; and stimulation by sunshine, fresh air, exercise, massage, and open-air treatment, with scanty clothing to increase heat loss from the skin.

### BLOOD CALCIUM AND INORGANIC PHOSPHATES IN CHILDREN WITH MARKED LACK OF MUSCLE TONE.

BY

LUCY WILLS, M.B., B.S. LOND.

(From the Biochemical Department, Hospital for Sick Children, Great Ormond Street, and the Pathological Department, Royal Free Hospital.)

It is well recognized that extreme lack of muscle tone is a characteristic accompaniment of bony rickets, and many consider this symptom as definitely part of the rachitic syndrome. This flabbiness is, however, characteristic of a type of child frequently seen in any out-patient department

and generally classified as debilitated, though when the child is under 3 the diagnosis of rickets is sometimes made on this flabbiness alone, even if there are no signs of either past or present bony rickets. This association of poor muscle tone and rickets suggests the possibility that the so-called debilitated flabby child may be suffering from mild rickets. It was with a view to testing this hypothesis that the present investigation was undertaken, which is only part of a general study of the "flabby child." Further, in a previous study,<sup>1</sup> when working in the Ear, Nose and Throat Department of the Royal Free Hospital, it was shown that children with true hyperplasia of the lymphoid tissue of the nasopharynx, as distinct from those with enlarged lymphoid tissue resulting from previous infection, had poor muscle tone. In fact, it was this study of the adenoid child that led to the present wider investigation.

#### NATURE OF INVESTIGATION.

Investigations of the blood in cases of rickets have shown characteristic changes: the serum-calcium value is more variable than in normal cases, and the average figure slightly lower, and the inorganic phosphates are in nearly all cases markedly lowered. A study of these two components was therefore undertaken in two control groups—one of normal children and one of sick children—and in a group of flabby children, to ascertain if there was any constant characteristic departure from the normal in the latter group.

The first control group (Group 1) consisted of twelve normal healthy children of the hospital class, aged 2 to 11 years. The second control group (Group 2) consisted of thirty-one children, aged 2 to 12 years, with enlarged and inflamed tonsils and adenoids, each of whom had, however, excellent muscle tone. This group was included not only to compare two groups of sick children, but also in the hope of obtaining further evidence in support of the classification of cases of adenoids into those with septic enlargement and those with true hyperplasia. The third group was made up of children, aged 1 to 12 years, with poor muscle tone. These cases were selected by Dr. Donald Paterson at Great Ormond Street Hospital, and had the following characteristics: soft flabby muscles, resulting in such abnormalities as large pendulous bellies, hollow backs, hyperextensible joints, and flat-feet; most had large tonsils. The children were brought to hospital for vague disorders, lassitude, or weakness. Children with any definite organic lesion were excluded from the series. No case with any suggestion of bony rickets was included.

#### METHODS.

Kramer and Tisdall's<sup>2</sup> method was used for the estimation of calcium in serum, and Briggs's<sup>3</sup> modification of the Bell-Doisy method for the inorganic phosphates in plasma. The plasma used for the phosphate solutions was always separated from the corpuscles within half an hour of drawing the blood; specimens showing any haemolysis were discarded. Owing to the difficulty of obtaining sufficient blood from small children both determinations could not always be done on the same patient.

#### RESULTS OF CALCIUM DETERMINATIONS.

Blood-calcium values for children have been determined by many authorities, and the majority are agreed that in normal children the serum-calcium value lies between 9.5 and 11.5 mg. calcium per 100 c.cm. of serum, with higher values in young infants. Jones and Nye<sup>4</sup> and Denis and Talbot,<sup>5</sup> using Lymau's method, report a much larger range, which has not been confirmed by other workers. Anderson,<sup>6</sup> working with whole blood, reports a wide range of normal values, but, as the question of corpuscular calcium is still in dispute, it is difficult to assess the value of her findings. In children suffering from rickets there is no very marked decrease in the serum-calcium values, such as is found in tetany and some cases of nephritis, but the range is much greater. Expressed in milligrams of calcium per 100 c.cm. of serum or plasma, the following ranges and averages are reported: Kramer, Tisdall, and Howland,<sup>7</sup> 8 to 11.1, average 8.6; von Meysenbug and co-workers,<sup>8</sup> 7.9 to 9.8, average 8.6; György,<sup>9</sup> 7.2 to 10.7, average 8.5. Mayer,<sup>10</sup> however, reports high serum-calcium values in early cases of florid rickets.

In the present investigation the blood-calcium values for the group of children with hypotonic muscles and for the control groups are set out in Table I. The values for the

TABLE I.—Blood-calcium Values.

	Type of Case.	Age.	No. of Cases.	Milligrams Calcium per 100 c.cm. Serum.		
				Lowest.	Highest.	Average.
Group 1	Normal	2-11	10	10.1	11.0	10.4
Group 2	Inflamed tonsils and adenoids but good muscle tone	3-12	20	8.7	10.6	9.8
Group 3	Poor muscle tone	2-9	30	6.6	10.6	9.0

Note.—If Groups 2 and 3 are combined as a control group the range becomes 8.7 to 11.0, with an average of 10.1.

normal children (Group 1) are, without exception, above 10 mg. per 100 c.cm. of serum, and range from 10.1 to 11.0 mg. The values for the other control cases (Group 2) have a lower average—9.8 mg. of calcium per 100 c.cm. of serum, with a range of from 8.7 to 10.6 mg.; only one value, however, was below 9 mg. The general health of the individuals of Group 2 varied; some were in good health at the time, although their tonsils and adenoids were enlarged as the result of previous infection; others, on the other hand, were in very poor condition, with acutely inflamed tonsils, aural and nasal discharges, etc., but all had excellent muscle tone. The cases with poor muscle tone (Group 3) gave serum-calcium values averaging 9.0, with a range of from 6.6 to 10.6 mg. per 100 c.cm.; of the 30 cases only 5 showed a value of 10 mg. or more.

It has been suggested that there may be a seasonal tide for calcium as well as for the inorganic phosphates of the blood (Hess<sup>11</sup>). The present study was made during the months of April, May, and June; no seasonal change was indicated during that period in any group, but the figures and time are both too limited for any deductions to be drawn.

#### RESULTS OF INORGANIC PHOSPHATE DETERMINATIONS.

The inorganic phosphate values in normal children, as established by various authorities, average for whole blood 4.0 mg., and for serum and plasma 4.1 mg. per 100 c.cm. With the exception of Jones and Nye<sup>4</sup> and of McKellips, De Young, and Bloor,<sup>12</sup> the latter working on infants, who give a range of from 1.9 to 5.4 and 1.2 to 4.6 mg. per 100 c.cm. respectively, authorities seem agreed that the normal range is from 3.2 to 6.5 mg. per 100 c.cm., but that the values are nearly always over 4.0 mg.

In contrast with the normal is the characteristic low value found in most cases of active rickets, uncomplicated by tetany. Howland and Kramer,<sup>13</sup> for example, give a range of from 0.6 to 3.2 and an average of 2.0 mg. per 100 c.cm. of serum; Anderson<sup>6</sup> gives from 2.5 to 5.3, with an average of 3.3 mg. per 100 c.cm.; György<sup>9</sup> gives from 1.6 to 2.9, with an average of 2.4 mg. per 100 c.cm.

In Table II are given the values for the inorganic

TABLE II.—Values for Inorganic Phosphate.

	Type of Case.	Age.	No. of Cases.	Milligrams per 100 c.cm. Plasma.		
				Lowest.	Highest.	Average.
Group 1	Normal	5-10	5	4.1	6.1	4.8
Group 2	Inflamed tonsils and adenoids but good muscle tone	3-12	20	2.9	5.1	4.1
Group 3	Poor muscle tone	1-11	25	2.5	6.1	4.5

phosphate in the three groups under consideration in the present investigation. There is no difference between the values in Groups 2 and 3; the figures in both groups cover the same range, and with five exceptions fall within the normal limit. The five normal cases comprising Group 1 give a slightly higher average, but a larger number might have shown a wider range. The findings are not such as would be expected if the condition in Group 3 (flabby children) is regarded as akin to florid rickets.

Kramer, Tisdall, and Howland<sup>7</sup> state that in normal blood the product of the calcium and inorganic phosphate values should be 40 or over, while in rickets it is reduced below this value. György<sup>8</sup> uses the quotient of the organic phosphate into the calcium values, and states that in normal cases this figure should be 1.95, in rickets 3.5, and in tetany 1.4. Five cases in Group 3 of the present investigation show a lowered product, but a lowered quotient also, due to the lowering of the calcium value, while the phosphate value remained normal. The quotient (with one exception, where it is 1.32), though lowered, is never as low as in cases of tetany, and the significance of this change is not evident.

#### CONCLUSIONS.

The serum-calcium values found in the group of normal children agree with those of other workers. The values obtained in Groups 2 and 3 show a wider range than the normal, the difference being more striking in Group 3 (hypotonic children) than in Group 2. In Group 3, moreover, the average calcium value is 9 mg., a slightly lower figure than the average of 10.4 found in the normal cases. Five cases in Group 3 have values of 10 mg. or more, and many other of the cases have but a slightly lowered value; and further, inversely, a few cases in Group 2 have lowered values though good tone. It is therefore clear from these two facts that muscle hypotonus is not immediately dependent on the serum-calcium level, as it can occur with either high or low values. A wide range of calcium values is probably constantly associated with this poor tone, even as a similar range has been shown to be associated with rickets, but it does not operate as a causative agent. The fact that Group 2 had a greater range than the normal suggests that such variation occurs in other conditions of ill health.

The inorganic phosphate figures for the three groups, with a few exceptions which occur both in Groups 2 and 3, fall within the limits of the normal and do not differ from each other. In contrast with these findings are those recorded in cases of bony rickets where low inorganic phosphate values are constantly found and are considered by most authorities as typical of the disease. Anderson,<sup>6</sup> however, as a result of her work on rickets, suggests the need for further investigation of blood phosphates in disease "causing and probably preceded by considerable muscular inactivity and atonicity," before deciding whether a low blood phosphorus is an exciting cause or merely a result of rickets. The normal values found in Group 3 (flabby children) are of interest in this connexion, as they do not suggest any association between lack of muscle tone *per se* and a low inorganic phosphate level in the blood, such as is frequently found in rickets.

The balance between the calcium and the inorganic phosphates, expressed either as the product or the quotient of the phosphate and calcium figures, does not appear to be appreciably altered from the normal in Groups 2 and 3, though there is a slightly greater range in the figures in Group 3, owing to the greater variability of the calcium figures. In fact the chemical findings reported above do not appear to support the hypothesis that muscle hypotonus in children is necessarily an indication of some degree of rickets, though the hypothesis can only be adequately tested by a study of the conditions in which these flabby children live and by the result of carefully controlled treatment.

#### SUMMARY.

1. The average serum-calcium value in 10 normal children (Group 1) was found to be 10.4 mg. and the range 10.1 to 11.0 mg. per 100 c.cm.; and in 20 cases with inflamed tonsils and adenoids but good muscle tone (Group 2) it was 9.8 mg., and the range 8.7 to 10.6 mg.
2. The average value found in 30 cases with marked lack of muscle tone (Group 3) was 9.0 mg., and the range 6.6 to 10.6 mg. per 100 c.cm.
3. The average value of the inorganic phosphates of the plasma was found to be approximately normal in all three groups (50 cases), and there was no difference in the range of values in Groups 2 and 3.
4. Though the calcium values were more variable in Group 3, no relationship between the calcium level in the blood and muscle hypotonus was established.

5. The blood picture of flabby children is not similar to that of rachitic children, though the calcium variation is the same in both conditions.

In conclusion I would express my thanks to Dr. Donald Paterson for selecting the cases of flabby children, to Mr. Gay French for permission to investigate his cases, and to Dr. Harrison for permission to work in the Biochemical Department, Great Ormond Street, and for his valuable help with this work.

## MIKULICZ'S DISEASE ASSOCIATED WITH ARRESTED MILIARY TUBERCULOSIS.

BY

T. W. PRESTON, AND B. L. JEAFFRESON,  
M.R.C.S., M.D., B.S. LON.,

RESIDENT MEDICAL OFFICER, HOUSE-PHYSICIAN,  
CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS,  
VICTORIA PARK.

THE following case seems to be of sufficient interest to merit publication.

E. D., a girl aged 15 years, was admitted to the City of London Hospital, having been diagnosed at her local tuberculosis dispensary as a case of early phthisis. Her history was that three months before coming under our observation she had gradually begun to feel weak and easily tired, developed a slight dry cough, and once brought up a few streaks of blood. At the same time she noticed a marked "puffiness" of the eyelids for which she was treated for subacute nephritis, a trace of albumin having been found in her urine at this time. In regard to her past history, she had been a healthy child except for measles, chicken-pox, and whooping-cough at 3 and 4; at 2, however, she had had a severe illness, the details of which are vague; apparently her chief symptoms were fever and acute pains all over, for which she was kept in bed for about three or four weeks. There was no family history of tuberculosis, and she had two brothers and a sister alive and well. The patient was rather pale, but otherwise did not look particularly ill. She had very little cough, she had no night-sweats, and her temperature was normal.

Repeated careful physical examinations showed a chest apparently little removed from the normal. A radiogram, however, showed the remarkable appearance seen in the accompanying figure, and was suggestive of an acute miliary tuberculosis. A diffuse miliary mottling is observed throughout both lung fields. The possibility that this appearance might have been due to an anthracosis was excluded by the fact that the patient had never been engaged in any dusty occupation. So inconsistent, apparently, was the radiogram with the

physical signs and the condition of the patient, that a second film was taken; this showed precisely the same state of affairs. A sputum examination showed tubercle bacilli present; subsequently, however, there have been seven successive negative examinations.

The second point of interest about this case was that there were found to be symmetrical enlargements of the

parotid, submaxillary, and lacrymal glands. The enlargement of these latter had apparently been much greater a few weeks prior to coming under our observation, and had no doubt given rise to the erroneous conclusion that the patient was suffering from kidney trouble. The swellings were smooth, uniform, and not fixed. It was thought that the accessory lacrymal glands were palpable, but not the socia parotidis. The glands of Blandin-Nuhn were distinctly felt as two round hard swellings at the tip of the tongue, as described by Ziegler.<sup>1</sup> The sublingual glands did not seem to be abnormal and the swellings sometimes said to be found on the hard palate were not observed. The liver and spleen were not enlarged; there were lymphatic glands palpable in the neck near the submaxillary glands, but otherwise the lymphatics did not appear to be affected. The tonsils had been removed some years previously. A blood count showed 5,600,000 red cells, haemoglobin 90 per cent., leucocytes 10,000. A differential count showed 62.5 per cent. polymorphonuclear leucocytes, 6.5 per cent. hyalines, and 31 per cent. lymphocytes. The urine was normal.

Since the syndrome of simple lymphomatous hyperplasia of lacrymal and salivary glands was first described by Mikulicz, many cases resembling but not synonymous with this condition have been recorded from time to time in the literature. Von Brunn has attempted to classify the various diseases associated with these symptoms as follows:

1. Cases without alteration in the blood—

(a) Without symmetrical swellings of the spleen or lymphatic glands.

(b) With swellings of the spleen or lymphatic glands.

2. Cases with alteration in the blood—

(a) Severe aplastic anaemia with lymphatic pseudo-leukaemia.

(b) Leukaemia.

Only cases coming under Group 1 (a) appear to be true cases of Mikulicz's disease. Campbell Howard collected 55 cases of this type down to 1909, but since then few, if any, cases have been recorded in the literature. The most recent contribution on the subject which we can find appears to be that of Thursfield in 1914,<sup>2</sup> and his case appears to have been one of "lymphatic pseudo-leukaemia." Our case certainly comes under Group 1, and, except for two doubtful glands in the neck, the lymphatic apparatus does not appear to have been involved.

The association of our case with a tuberculous condition of the chest is interesting, for whilst the majority of cases appear to be a simple chronic interstitial inflammation, non-tuberculous (Igersheimer and Pollot),<sup>3</sup> both tuberculous (Krausheimer, Pitt, and Napp)<sup>4</sup> and syphilitic cases (Lange, Luders, Gutmen, and Jackobaus)<sup>5</sup> have been recorded from time to time.

#### PROGNOSIS AND TREATMENT.

According to Thursfield,<sup>2</sup> prognosis is bad in the leukaemic and pseudo-leukaemic, but appears to be good in true cases of Mikulicz's disease. Arsenic and potassium iodide are usually recommended in treatment. The results of operative intervention appear to have met with different results in the hands of different observers. Ziegler records how removal of one of the enlarged glands has resulted in great increase in the size of the rest. Elliot, on the other hand (*Ophthalmoscope*, 1911),<sup>3</sup> has recorded a case in a Hindu woman in which operation on the lacrymal glands was successful and was followed by diminution in the size of the parotids and submaxillaries. In view of the uncertain results of the cases recorded we have not thought operation justifiable in our case, especially as the swellings are giving rise to no unpleasant symptoms; we are simply giving arsenic and potassium iodide. X rays have met with success in some cases.

In regard to the remarkable chest condition revealed by the skiagram such cases have been recorded before. H. K. Dunham and J. H. Skavlem<sup>4</sup> say:

"Many cases of healed military tuberculosis are being found by our more general use of the x-ray chest studies. This diagnosis is only justified when the subject gives no history of work in a dusty trade. Lungs of anthracite miners most nearly simulate military tuberculosis. The x-ray picture is that of fine, sharp, discrete studdings, more or less evenly distributed throughout all lobes. . . . Most peculiarly these patients seldom, if ever, give any history suggesting serious lung infection."

The undiagnosed illness with which the patient was affected at the age of 2 is not without interest, however, although its significance is difficult to estimate. Opie<sup>5</sup> has noted in several necropsies extensive calcified tubercles of the lung and lymph nodes, so that "a grave infection must have existed at some time previous—even though there had been no history of corresponding symptoms, there was doubtless at some period imminent danger of death from tuberculosis."

Prognosis is necessarily uncertain from lack of experience of similar cases. Dunham<sup>4</sup> considers that such patients are likely to go downhill rapidly if they become subsequently infected.

We are indebted to Dr. Clive Riviere for permission to publish this case; to Dr. Sparks, who took the x-ray film; and to Dr. D. S. Page, who did the blood count.

## Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

### HERPES ZOSTER AND VARICELLA.

As the relationship of herpes zoster and chicken-pox is still undecided, I desire to place the following case on record.

On December 19th, 1924, a woman developed herpes zoster. On January 3rd, 1925, her son, aged 5 years, was covered with a typical rash of chicken-pox. The following facts seem to point to some relationship between the two diseases:

1. The boy had not been away from his own home for several weeks.
2. There is not a case of chicken-pox in his neighbourhood, so far as I can ascertain.
3. The child slept in a cot in his mother's room.
4. The fourteen days' interval between the onset of the two diseases agrees with the incubation period of chicken-pox.

On the other hand, if there is any relation between herpes zoster and chicken-pox, it is strange that the coincidence of the two diseases should be so infrequent. This is the first occasion that I have seen them occur in the same family at the same time.

### RUPTURE OF ABDOMINAL WALL WITH PROTRUSION OF UNINJURED INTESTINE.

THE interest of the following case appears to me to lie in the fact that a crushing injury of the abdomen could produce a rupture of the abdominal wall and protrusion of the intestines without injury to the intestines or other viscera, as is usually found.

A boy, aged 16, was admitted to hospital on October 3rd, 1924. He had been crushed between the buffers of two railway wagons, and it was found on examination that about three feet of small intestine protruded through an opening below the tenth rib in the mid-axillary line.

The patient was anaesthetized and several small lacerated wounds were found in the skin, through one of which the intestine was protruding. On feeling the skin there was a gap, four inches in length, two inches wide, in the muscular layers and the abdominal wall, with great laceration of the peritoneum. The protruding intestine appeared to have escaped injury, and was returned to the abdomen. The eleventh and twelfth ribs were fractured and the distal portions of these were removed. After excising all damaged tissues the layers of the abdominal wall were brought together with difficulty and closed. A laparotomy through a left paramedian incision was then performed to exclude injury to abdominal viscera, but nothing abnormal was discovered except some retroperitoneal haemorrhage, not extensive.

The boy made an uninterrupted recovery and his abdominal wall is now perfectly sound with no bulging at the site of the injury.

### MYELOID LEUKAEMIA ENDING AS LYMPHATIC LEUKAEMIA.

The case reported below is interesting because of the remarkable reduction of the myeloid leucocytes from 892,000 to 11,600, with corresponding recovery of health, so that the man was able to return to work. It was very disappointing that acute lymphatic leukaemia should have supervened, as it is not primarily a disease of the bone marrow like the myeloid condition. This case is not a solitary coincidence, since, a few years ago, another patient with myeloid leukaemia, whom I had successfully treated with x rays, also died of lymphatic leukaemia.

A man, aged 38, was admitted to hospital under me in February, 1923, with an enormous spleen extending into the left iliac fossa. His blood count was: red cells 2,820,000, leucocytes 892,000 (polymorphs 44 per cent., lymphocytes 16 per cent., eosinophils 4 per cent., mast cells 4 per cent., myelocytes 32 per cent.). There were several small retinal haemorrhages, and, soon after admission, he developed a large haematoma beneath the left scapula. This became so painful that 12 oz. of altered blood were aspirated from it; it filled up again, however, but with less pain. It was slowly absorbed, lasting in all about three months. The treatment employed was exposure to x rays twice weekly of the heads of the long bones at the knees, hips, and shoulders, and of the spleen, the dosage being arranged by Dr. W. B. Prowse. The leucocytes steadily diminished in number, rather more rapidly when arsenic was given as well as the x-ray treatment. The man's condition also improved and his spleen became much smaller.

In February, 1924, his blood count was: red cells 4,030,000, leucocytes 56,100 (polymorphs 73 per cent., lymphocytes 2 per cent., eosinophils 2 per cent., mast cells 7 per cent., myelocytes 16 per cent.), and he was able to do light work. In July he was strong and well, and the spleen was only an inch below the costal margin. The blood count then was: red cells 4,856,000, leucocytes 11,600 (polymorphs 76 per cent., lymphocytes 5 per cent., mast cells 11 per cent., myelocytes 1 per cent.), and the x-ray treatment was suspended. At the beginning of September he became rapidly short of breath and very anaemic. His blood count was then found to be: red cells 2,760,000, leucocytes 160,000 (lymphocytes 94 per cent., polymorphs 4 per cent., and myelocytes 2 per cent.). He died of this acute lymphatic leukaemia in three weeks.

Physician to the Royal Sussex County Hospital.

### GASTRIC CANCER TREATED BY PYLORECTOMY AND GASTRO-ENTEROSTOMY.

The case here recorded is of interest on account of the following peculiar characteristics: (1) the very unusual amount of peristalsis definitely ending in the tumour; (2) the extensive mobility of the growth; and (3) the absence of glands, adhesions, or ulceration, yet almost total occlusion of pylorus.

A. T., a lady aged 72, consulted us in December, 1924, complaining of obstinate vomiting; food was rejected immediately after being taken. No history of haematemesis was given. She had constant epigastric pain, and had lost a considerable amount of weight. The symptoms were of three months' duration. Examination of the abdomen revealed marked peristalsis, the waves showing a rise of one inch above the surrounding abdominal wall. A definite tumour, the size of a hen's egg, was palpable under the right rectus. It was firm and freely movable in all directions. Splashing was distinctly audible on palpating the stomach, and the peristaltic waves could be felt to end at the tumour. There was no free fluid in the abdomen, no glands were palpable, and there was no enlargement of the liver.

**Operation.**—A right rectus incision was made, and the muscle retracted outwards. The tumour was found to be the pylorus; it could be easily lifted out of the abdomen. There was no evidence of adhesions or glandular involvement. The liver was normal. The stomach was much enlarged and thickened. Posterior gastro-enterostomy was first performed, as it was doubtful how the condition would stand resection, but when it was found that her condition was favourable we proceeded to remove the pylorus, one inch of the first part of the duodenum, and as much of the pyloric end of the stomach as possible.

Recovery was uneventful, and when she left the nursing home nineteen days later she was able to eat full diet with no discomfort.

Examination of the specimen showed that the mucous membrane was intact over the tumour area; there were no signs of previous ulceration. The pyloric canal was almost completely occluded. The carcinoma presented colloid

## Reports of Societies.

### POST-OPERATIVE PULMONARY AFFECTIONS.

A COMBINED meeting of the Sections of Surgery, Anaesthetics, Medicine, Obstetrics and Gynaecology, and Pathology of the Royal Society of Medicine was held on February 4th to discuss "The prevention and treatment of post-operative pulmonary affections." Mr. H. J. PATERSON was in the chair.

Mr. E. C. LINDSAY said that there was a growing belief that post-operative lung complications, such as pneumonia, pleurisy, and collapse, which had been a source of contention and mutual reproach between surgeon and anaesthetist, were not the result of irritation or congestion, but were in fact the result of pulmonary embolism and infarction. Wharton and Pierson considered that 40 per cent. of pleurisies and 12 per cent. of pneumonias after gynaecological operations were due to pulmonary embolism. Such embolism might be of (1) the massive type, occluding one or both pulmonary arteries; (2) the infarction type, followed by pleurisy and signs of consolidation; (3) the type where the site of the embolus prevented its recognition as such; this type was associated with slight respiratory increase, mild evening pyrexia, and the expectoration of small quantities of blood and mucus. Two cases were quoted in which this third type of embolism had served as a warning—in one case of the massive embolism that occurred later, and in the second case of thrombosis of the veins of the leg. It was noteworthy that in many cases a premonitory sign of the massive type of embolism was an urgent desire to defaecate, and the speaker suggested that this might be due to a vasomotor reflex set up by the passage of the clot from the femoral or iliac veins. Sir Charles Gordon-Watson and Wharton and Pierson had emphasized the importance of the slight evening rise of temperature as a constant premonitory sign. A research into the records of surgical cases at the London Hospital for the years 1914-24 revealed 114 undoubted cases of pulmonary embolism. It had been stated that this unfortunate condition was increasing, and changes in blood character and coagulability depending on changes of diet had been suggested as a cause. But in Mr. Lindsay's opinion the increase was more apparent than real, since the percentage in the London Hospital cases agreed very closely with Rupp's figures as the result of the investigation of over 22,000 operations from 1903 to 1920. Rupp also found that the mortality of pulmonary embolism in internal disease without operation was 1.1 per cent.—four times as high as that following operation. An analysis of the London Hospital cases showed that age was a very important factor, the average for the series being 52 years. The average of urinary bladder and prostate operations complicated by pulmonary embolism worked out at 60 years, and even in appendicitis the average age was 30.4 years, although there were included among them cases whose ages were 2½, 11, and 13 years. As regards the different types of operations which were responsible for embolism, 21 cases occurred in 2,778 gastric operations, 22 cases in 2,004 major gynaecological operations, 17 cases in approximately 4,000 appendix operations, and 12 cases in 1,967 hernia operations. As in other published series, gynaecological operations therefore headed the list in order of frequency. *Post-mortem* examination revealed thrombosis in 42 per cent. of the cases, the thrombosis being in the left common iliac or left iliac vein in half of these cases. Thrombosis of the pelvic, iliac, and femoral veins was found in 47 per cent. of the gynaecological cases, and 57 per cent. of the gastric cases. This was remarkable, since in one case the operation involved the systemic venous system and in the other the portal system. In none of the *post-mortem* notes was there any mention of extensive thrombosis at the site of operation. The question of primary pulmonary thrombosis had been discussed by Professor Glynn and others, but the speaker found it difficult to reconcile the size of the thrombus, its considerable length, its frequently unbranched appearance, and the fact of its being nearly always rolled up, with the formation of the clot in the

pulmonary artery. Further, the pulmonary artery, though carrying venous blood, was arterial in type.

Dr. F. E. SHIPWAY said that the two outstanding post-operative pulmonary complications—bronchitis and pneumonia—occurred more frequently after abdominal, and especially upper abdominal, operations than after operations elsewhere, and were very rare in private practice. Bronchitis, although not often directly fatal, was a very serious complication in the unit. It sometimes arose in a mild degree in a perfectly healthy patient after ether anaesthesia, and was caused partly by exposure, but chiefly by the cooling and irritating effects of high concentrations of ether vapour, which lowered the resistance of the lung tissues to bacterial invasion. Further, deep anaesthesia abolished the reflex mechanism and caused an appreciable fall.

For these reasons, the speaker considered that deep ether anaesthesia was harmful, and was definitely contraindicated in cases of bronchitis and asthma. Except in the summer months ether should be given warmed. The relative immunity of private patients from post-anaesthetic pulmonary complications was ascribed by Dr. Shipway to the better nursing conditions after the operation. Hospital patients nursed in large wards were exposed to draughts and kept in an atmosphere that was not sufficiently warm, whereas private patients generally had a room the temperature of which could be kept at the optimum to suit the case. Again, the importance of obtaining a history of recent common cold, and of not giving an anaesthetic except in emergency when such a history was obtained, was not sufficiently recognized in hospital practice. Liability to bronchitis and pneumonia was very much less after non-abdominal operations, even though ether was given; further, pulmonary complications not uncommonly occurred after abdominal operations when a local or spinal anaesthetic had been given. From this it was evident that there was some factor for which the site of operation was responsible; this was, he thought, collapse of the lung, massive or partial. Pasteur, Whipple, Elwyn, and others had studied this subject, and concluded that collapse, usually partial but occasionally massive, of the lower lobes of the lungs was a common predisposing factor in the production of post-operative bronchitis and pneumonia. The mechanism of this collapse, whether due to reflex inhibition of the diaphragm, sudden blocking of the bronchioles by secretion, sudden reflex spasm of the bronchioles, or surgical paralysis of the abdominal muscles, was not clear, although recent observations pointed to a nervous origin. The value of local anaesthesia in preventing pulmonary complications had been challenged, but its growing use in America seemed to indicate that it was less dangerous, although the exposure involved in certain methods of local anaesthesia might be as great as that of general anaesthesia. For operations below the umbilicus Dr. Shipway advocated spinal anaesthesia combined with gas and oxygen or a minimum quantity of C.E. mixture. In 258 bladder cases anaesthetized thus only two died from pulmonary complications. Cyanosis and excessive secretion of mucus were harmful, and if the latter occurred hypodermic injection of atropine should be given after the anaesthetic. Expansion of the base of the lungs by breathing exercises should be begun twenty-four hours after the operation, and depressant drugs, such as aspirin and morphine, should be given as sparingly as possible, since pain had its use in promoting movement.

Mr. J. P. HEDLEY said that gynaecological operations were reputed to be more commonly followed by fatal pulmonary embolism than any others, but the records of St. Thomas's Hospital did not show any greater frequency in the gynaecological department than in the surgical. The figures of the Mayo Clinic showed 10 fatal cases in 7,993 gynaecological operations—about 0.12 per cent., while there were 23 in 12,229 operations on the gall bladder, liver, prostate, colon, and rectum, and for hernia—about 0.18 per cent. The great difficulty in the prevention of pulmonary complications after operation was that their causes were not definitely known. Some thought that nearly all the cases resulted from embolism, and others that they were due to disturbances of anaesthesia. When a patient had a common cold the dangers of lung distur-

ances after anaesthetics were well known, so that Mr. Hedley saw no difficulty in assuming that many post-operative pulmonary complications were due to the stirring up of a latent infection of the lungs by the anaesthetic. Old people were particularly liable to post-operative lung complications. There were many arguments in favour of the embolic theory, notably that operations on certain regions of the body, even after local anaesthesia, were more likely to be followed by disturbances than others. But often after examination under an anaesthetic there had been pulmonary disturbances, while the freedom from these dangers after accidental wounds and fractures was striking. Assuming that most of these cases starting with bronchitis were due to the disturbance of the anaesthetic and certain predisposing causes, reasonable precautions could be taken. When the lungs were damaged either operation should be avoided or it should be performed under a local or spinal anaesthesia, and deferred if the patient had a cold. The temperature of the theatre should be 70° F., and after operation the patient should be protected from draughts and cold. At St. Thomas's a tent was placed over the trolley on which the patient returned to the ward, and strict rules were enforced about bed curtains. This had reduced the number of these "bronchitis" cases. The inhalation of vomit, mucus, or blood should be prevented while the patient was semi-conscious. When pulmonary complications developed later the only explanation seemed to be embolism or thrombosis. There was some evidence that particles of tissue detached by the operation were carried to the lung and held there by the lung capillaries. Thrombosis in veins near the seat of operation might be the source of emboli, and where even mild sepsis was present this likelihood was greater. Those cases where the patient had an attack of pain over a small area of the chest, followed by signs of pleurisy near this area, were fairly common. There was usually some evidence of mild infection of the wound, such as moderate disturbance of temperature, or vaginal discharge after total hysterectomy. The obvious way of preventing complications in this type of case was to avoid damaging or bruising tissues around the seat of operation. The treatment when an attack had occurred was by local applications to the chest wall and by keeping the patient at rest in bed. In those cases where sudden large pulmonary embolism occurred there was usually very little to attract attention beforehand, although there was often a mild disturbance of temperature. A patient who had suffered from haemorrhage before or at the time of operation was more liable to thrombosis. Starvation and excessive purgation before operation might both add to the risks of thrombosis in any part of the body. When patients were lethargic after operation there was increased fear of this complication. To prevent it operations for conditions such as uterine fibroids, which produced anaemia, should be performed before the patient had become very anaemic; loss of blood at operations should be properly controlled. Bruising of the tissues must be avoided by the greatest tenderness in handling.

Mr. Hedley thought that the old method of administering drastic purgatives before operation was useless and dangerous. Patients should be encouraged to move their limbs, and should be propped up in bed within a day or two of operation. He said that the dyspnoea and shock produced by a pulmonary embolus was due to the sudden embarrassment of the right side of the heart, and if the patient could be tided over the first few hours there was good chance of recovery. Blood-letting and the inhalation of amyl nitrite were the best methods of treatment, but morphine also was most valuable. Although in the routine management of post-operative cases the patients should be encouraged to move about, once it was thought that a clot had formed the patient should be kept absolutely at rest.

Lord Dawson said that enormous improvements had taken place in anaesthesia in recent years, due to improved administration and better care of the patient. He thought that the anaesthetist was now seldom responsible for serious post-operative complications such as pulmonary embolism. Small infarctions, especially if deep, might give rise to no visible signs, and he suggested that they were more frequent

than was supposed and a frequent cause of post-anaesthetic bronchitis and pneumonia. If the infarction became infected a pneumonic patch was formed. It was interesting that the type of pneumococcus was almost invariably Type IV. While physical signs from a small infarction were almost absent, the symptoms might be very severe, and were possibly due to a form of shock. Emboli generally arose from the systemic veins, particularly the femoral and iliac, and only very rarely came from the auricles and valves of enfeebled hearts. These complications did occur after local anaesthesia.

Sir CHARLES GORDON-WATSON referred to a paper on this subject by Featherstone, who found that 10.8 per cent. of 222 consecutive severe abdominal operation cases developed pneumonia, whereas only 0.7 per cent. of 2,100 orthopaedic operations had developed this complication. There could be no doubt that operations on the upper abdomen were much more prone to produce pneumonia than any others, and this might be due, as Pasteur had pointed out, to the interrelation between the muscles of the abdominal wall and the diaphragm. During the war collapse of the right lung was very commonly seen after wounds in the abdomen. Collapse was followed by stasis in the collapsed lobe of the lung and then by infection. To prevent this, irritation by the anaesthetic should be avoided, and the experience of the war went to show that nitrous oxide gas and oxygen with some ether was the most satisfactory anaesthetic for the prevention of shock during the operation and post-anaesthetic lung complication. As regards pulmonary embolism, the figures at St. Bartholomew's Hospital tended to show that the massive type was increasing in frequency, although still happily very rare, there having been 32 deaths from this cause in 29,000 operations. Small infarctions were often indicated by a slight evening rise in the temperature. He thought that the clots which broke up and gave rise to small and possibly repeated infarctions were infected, whereas the clot responsible for the massive infarction was generally sterile. Clotting might be due to trauma at operation, stasis, and possibly the absorption of thrombokinase, and should be guarded against by avoidance of excessive loss of fluid and shock during operations, and by attention to posture during and after operations.

Dr. H. W. FEATHERSTONE said he had published figures showing the extreme frequency of post-operative pneumonia after operations on the upper abdomen, and the infrequency of this complication after prolonged operation on the head and neck. He felt that ether should not be specially blamed for these complications, and indeed considered intratracheal ether to be a very safe anaesthetic, very infrequently followed by pneumonia. In cases where pneumonia arose the previous history of the patient should be investigated. During influenza epidemics these complications occurred more frequently, and he therefore strongly urged the advisability of not performing severe abdominal operations at such times except in emergency.

Dr. ROBERT HUTCHINSON considered that thrombosis was often postural and due to the adoption of the Fowler position, which also had the disadvantage of exposing the patient's chest. If this position must be adopted, the patient should be encouraged to wear a warm jacket, and "fresh air" must be allowed for the time to go "by the board."

## SEPTICAEMIA AS A COMPLICATION OF MIDDLE-EAR INFECTION.

At a meeting of the Section of Otology of the Royal Society of Medicine on February 7th, with Dr. J. KEER LOVE in the chair, Mr. G. J. JENKINS read a paper on septicaemia as a complication of middle-ear infection.

Mr. Jenkins said that the term "septicaemia" denoted an infection of the blood; clinically it implied a general infection, its severity ranging from a slight disease with apparently unimportant symptoms to a grave condition with a fatal termination. The one absolute proof of true septicaemia was the finding of organisms in the blood; he had encountered only two groups of organisms in true septicaemia—namely, streptococci and pneumococci. In his experience septicaemia, or the septicaemic state, was

almost as common in acute middle-ear infection as any single intracranial complication. There was a real danger of failure to recognize the middle-ear infection in the early stages of septicaemia, when something might be done to save the patient. Septicaemia was probably more common with infections of the ear, nose, and throat (especially of the ear), than with inflammation of any other part of the body, including the pelvis. Intracranial complications of middle-ear disease were becoming less common, but he believed that the septicaemia in association with aural sepsis was less likely to disappear, occurring as it did in the very early stages of the infection. Septicaemia, or the septicaemic state, was more likely to be met with in children than in adults, and, he believed, more commonly in patients who had not previously had a gross lesion of the ear. Mr. Jenkins gave details of a typical case of the milder type of the septicaemic state, in which the aural symptoms and signs were so masked that he had at first believed that some other cause must be sought. In such cases, when septicaemia appeared the symptoms and signs of inflammation at the primary site of infection were profoundly modified. When the primary lesion was in the middle-ear tract the clinical appearances depended on the stage reached of the inflammation and the anatomical formation of the mastoid. If the incidence of septicaemia coincided with a later stage of inflammation, the appearances might be those of chronic suppurative middle-ear disease. As seen during an operation the appearance of the interior of the mastoid was characteristic: the "laking" of the pus in the larger cells, the thin, pale mucous membrane lining the cells almost normal in appearance, and the absence of congestion were characteristic of mastoiditis followed by a septicaemic state. Such an appearance at operation had on occasion suggested to him a diminished resistance, and this had been confirmed by a low leucocyte count. After operation the general symptoms predominated, and there was no evidence of reaction in the wound. A smear from the wound might show a few lymphocytes, polymorphonuclear cells, and a large number of organisms. In regard to diagnosis Mr. Jenkins attached a good deal of importance to the cytological examination of the blood, especially the leucocyte and differential counts. The value of the bacteriological examination of the blood was very great when the result was positive, but little when it was negative. As regards treatment, it was very important that the middle-ear condition should be thoroughly dealt with. In the majority of cases this involved the Schwartz operation and paracentesis; then came the question of the treatment of the general infection. Until recently Mr. Jenkins had been accustomed to give these patients large doses of normal horse serum as soon as possible, continuing this daily so long as necessary; lately he had been trying immuno-transfusion. His own experience of vaccine therapy had been unfortunate. Mr. Jenkins wished to draw the attention of general physicians to the importance of examining carefully the ears, nose, and throat when a patient was in this septicaemic state.

### Nerve Anastomoses.

Mr. LIONEL COLLEGE and Dr. L. D. BAILEY exhibited a kinematograph film illustrating anastomosis of the facial nerve in cases of facial palsy. The film consisted of four parts: the first part showed a typical case of facial palsy, and the three subsequent parts showed three cases of nerve anastomoses for facial palsy, after operation. The film brought out well the slight differences still remaining in the movements of the opposite sides of the face; and clearly showed how re-education of the affected side was effected after nerve anastomosis. The value of the kinematograph in demonstrating post-operative results and the signs of affections of the nervous system was strikingly exhibited, the photography being excellent.

In the first case of nerve anastomosis shown, a girl aged 17, the reaction of degeneration had been still complete, with no evidence of recovery, at the end of six months after an operation for suppurative in the labyrinth and meningitis. The facial nerve was anastomosed end to end with the whole of the central end of the hypoglossal, and the peripheral end of the hypoglossal was implanted laterally into the spinal accessory. The film showed the state of the face three years after nerve anastomosis; faradic response was present in all the facial muscles. In the second

case, a man aged 27 had a complete facial palsy resulting from a radical mastoid operation performed in India two years previously. The facial nerve was anastomosed to the whole of the central end of the hypoglossal. The descendens noni was divided and its central end was united with the peripheral end of the hypoglossal, the peripheral end of the descendens noni being implanted into the side of this junction. The film showed the state of the face fifteen months afterwards; faradic response was present in all facial muscles. The third case was that of a woman aged 56, who had a complete facial palsy after a radical mastoid operation. The facial nerve was attached to the central end of the descendens noni, and the peripheral end of the descendens noni implanted into a slit in the side of the hypoglossal. The film showed the state of the face after twelve months; there was faradic recovery of all the facial muscles.

## THE CONTROL OF TUBERCULOSIS AND THE MILK SUPPLY.

A MEETING of the Sections of Epidemiology, Comparative Medicine, and Disease in Children of the Royal Society of Medicine was held on February 9th, the chair being occupied by the President of the Section of Comparative Medicine, Professor F. T. G. HODGKIN.

Dr. JOHN ROBERTSON (M.O.H., Birmingham) said there was a widely divided amount of scientific medical opinion as to the part played by tuberculosis of bovine origin in the production and dissemination of the human disease. Some estimated that 3,000 human lives were lost annually owing to tuberculosis of bovine origin, and probably many thousands of children had other forms of tuberculosis due to the bovine bacillus which, though not fatal, caused crippling, glandular enlargements, etc. On the other hand, some experienced physicians held that the mild invasion of the bovine bacillus conferred just that amount of immunity which saved enormous numbers from acute tuberculosis of human origin. He emphasized the close clinical, pathological, and etiological resemblances existing between the lesions and the progress of the disease of the two kinds; the same predisposing factors also operated. Birmingham had attempted three methods. One was the testing of samples of milk for the presence of tubercle bacilli and the elimination of cows returned as positive. Another was an offer to farmers to test their herds free of charge if they would eliminate reactors. Thirdly, they had instituted pasteurization of milk with the view to limiting the amount of milk which was infected. Of the churns of milk sent into Birmingham during the past eighteen years 8.7 per cent. contained living tubercle bacilli, and the percentage so contaminated now was less than eighteen years ago. Many cows were eliminated as "wasters," and for this a small compensation was paid to the farmer as an inducement to have these animals quickly slaughtered. Before the war, as a result of the efforts of the city council, twenty-eight herds supplying milk to the city were free of tuberculosis, and many farmers at that time asked to come into line with the scheme. The results of the application of the tuberculin test by an experienced officer were very satisfactory, and for cowshed work it was quite reliable. On the average in dairy herds the reactors numbered 30 per cent. of the whole. His recommendation had been to pasteurize and bottle the milk, largely based on the great success achieved in cleansing the milk supply in America. He had never found living tubercle bacilli in milk which had been efficiently pasteurized. Of the milk supplied to Birmingham 70 per cent. had been sufficiently heated to kill tubercle bacilli, and he hoped that in a few years no milk would be supplied in the raw state except from tested herds. He thought persons handling milk should be examined once a week to ensure that they were free of disease. There was much needed here a careful investigation as to the merits of pasteurization and sterilization, and whether boiling destroyed or greatly diminished the vital properties of milk. During ten years Birmingham had 1,000 fewer cases of pulmonary tuberculosis notified, and the deaths from non-pulmonary tuberculosis were now only half the general rate for England and Wales.

Lieut.-Colonel BRITTLERANK (veterinary officer, Manchester) said the main fact for consideration in this discussion was that the tuberculosis of bovines was transmissible to human beings, and there was a good deal of evidence that such infection from bovine sources was, in many cases, of more virulent type than that originating

from another human. The associated economic problem as it affected agriculture was one of great importance, and it was upon that industry that the cost would largely fall. Roundly, there were in Great Britain  $7\frac{1}{2}$  million head of stock, 3 million being cows and heifers in milk or in calf. On the average, one-third of these were tuberculous, so that a million head of the dairy stock of the country were tuberculous in some degree, as ascertained by the tuberculin test. Some considered that encapsuled lesions of tuberculosis were a source of protection to the animals, and that the bacilli were frequently discharged into milk without there being detectable disease of the udder. But it was important to bear in mind that udder infection was usually secondary to lesions in the thorax, abdomen, and elsewhere in the body. Approximately 10 per cent. of the samples of Manchester milk examined during the past twenty-three years caused tuberculosis experimentally, and the percentage of farmers sending tuberculous milk into the city was higher in 1923 than it was in 1901. On 800 farms sending tuberculous milk, 597 cows were found to have tuberculosis of the udder, and when the disease was ascertained they were removed from the source of supply. In regard to more than 200 cons, there was ample evidence that just prior to the visit of the inspector they were disposed of to dealers. He believed that, as a general rule, the public would continue to buy the milk which was cheapest. The animals which earliest reacted to tuberculin were those giving the greatest quantities of milk—that is, those which worked the hardest. He advocated breeding their own stock, and stopping importation of strange cows, as one infected animal quickly carried its bad effect to the herd. That was carried out on one farm, and there was an increase of milk yield per cow per year of 200 gallons; moreover, on that farm there were no cases of contagious abortion. He had visited 136 farms: 6 were clean, 52 fairly clean, 78 dirty. At only 5 of the farms was there satisfactory provision for storage of manure, at 12 it was less satisfactory, and in the remainder such provision was either absent or very unsatisfactory. Of 346 cowsheds examined, 10 were clean, 147 fairly clean, the remainder dirty. He had ascertained that just prior to some of his visits farmers had sold tuberculous cows at prices ranging from 10s. to 35s. each. He said he hoped the Tuberculosis Order would soon be reintroduced, and would be so amended that it would require the inspection of every dairy farm in the country, without awaiting notification of disease. It was a waste of public money to pay compensation for infected cattle; it should be regarded as a crime for any man to be found in possession of such an animal on his farm. He believed there was no method by which really dirty milk could safely be made fit for human consumption.

Professor S. L. CUMMINS agreed that wherever in the world there was a practical absence of tuberculous cattle, there the human type of the disease was of a very grave and acute character; that was the case in large tracts in Africa, and in India. Thus, by concentrating on getting rid of tuberculosis one might possibly be doing harm; yet if this idea were disseminated, it might be retorted that thereby retrogressive farmers were being sustained in their attitude. Hence it was undesirable to make public any but well ascertained facts. He did not think sufficient attention was paid to the quantitative aspect of the question. Cobbett related that the Royal Commission reported the fact that the dose of tubercle bacilli which could infect a cow when ingested was infinitely larger than the dose needed to cause the disease when inhaled. Was not the aim of getting rid of all the bacilli from milk therefore rather theoretical? He believed the mixing of milk was of great importance in the prevention of tuberculous disease from that source, the uncontaminated milk acting as a wholesome diluent. It was said that 25 per cent. of the samples of London milk contained some tubercle bacilli, and guinea-pig experiments were positive with those samples, so that the safety of the milk as a whole must have been greatly increased by the mixing of milks. From 60 to 80 per cent. of the adult general population reacted to tuberculin, yet no doctor hesitated to advise mothers to suckle their children, without an examination previously to giving the advice, unless they were obviously ailing. The whole production of milk was a very artificial matter,

following on the breeding of cattle with this object in view, and the manipulations of the udder in frequent milking might tend to activate lesions there which would never have developed otherwise. He thought the gold salt recently discovered and tried in Copenhagen held out a hope of the cure of tuberculosis. He advocated a closer co-operation between the medical and veterinary professions in this matter.

Dr. NIVEN (late M.O.H., Manchester) related his experiences in this connexion in Oldham, and later in Manchester. At the former town he was responsible for the issue of a circular advising that all cow's milk should be boiled before use, and when he went to Manchester in 1894 he took the same course. The milk then supplied was so dirty that he could think of no other way of saving the people from the effects of drinking such a fluid. He referred to the able assistance given in the crusade by Professor Delépine. There were also instituted in Manchester classes of senior girls for instruction on the care and feeding of infants. He agreed that once tuberculosis was imported into a previously tubercle-free herd, the spread among the other animals was very rapid. Great precautions were needed to keep a herd free from the disease. In America the control of the milk supply was much more successful than in this country, and a large factor in the more satisfactory serving of the milk was the free use of ice, which would be a factor of much greater difficulty here. He expressed the hope that the programme put forward by the Astor Committee would be energetically put into operation by the Ministry of Agriculture. In New York the milk coming into the city was graded, three degrees being recognized, and he asked whether some such system might not be brought into operation in the largest cities here. Perhaps the country was not yet ready for such a measure, but it was likely that in five years something of the sort might be possible. There should be a corps of veterinary inspectors visiting all the farms which were supplying milk to cities, and reports should be regularly furnished by them to the city committees responsible for these matters. He believed greatly in the education of all who were concerned in the milk industry, both by tuition and, where needed, by coercion. In America the various States vied with one another in sending pure milk, and the authorities there did all they could to assist farmers to perpetuate the best stocks.

The discussion was adjourned to March 2nd.

### THE TREATMENT OF LYMPHADENOMA.

At a meeting of the Medical Society of London, held on February 9th, with the President, Dr. EUSTACE M. CALLENDER, in the chair, a discussion was held on the treatment of lymphadenoma.

Sir THOMAS HORDER opened the discussion by explaining that he had recently had under his care two patients suffering from lymphadenoma of the Pel-Ebstein type who were alive and well some considerable time after the illness first commenced. He considered that the treatment adopted in these cases was of general interest in that, he believed, no previous case of cure of this type of the disease had been recorded. The first case was that of a man, aged 47, whose illness commenced insidiously in 1918 with periodic bouts of pyrexia. These were found to be of a regular periodicity, occurring every fourteen days; on examination, both between and during the attacks, nothing definite could be found. Spending the winter abroad had no effect on the disease, and at the end of eighteen months an exploratory laparotomy was performed, mainly because of some rather vague symptoms in the region of the liver. Nothing abnormal was found, except some adhesions round the gall bladder and round the appendix, which was removed. A temporary cessation of the attacks of fever, lasting for six weeks, followed, and a second operation produced no improvement. In 1922 arsenic treatment was instituted and neokharsivan was given intravenously in increasing doses at intervals of five days, followed by applications of  $x$  rays to the liver. The next attack of fever was abortive, but the following one was as severe as ever, and the attacks continued, although the rhythm was not so regular. Further applications of  $x$  rays were made, but the condition

remained unchanged, and a course of "protein shock" therapy, consisting of intravenous injections of peptone, was without effect. Another intensive course of neokharsivan was next tried, with  $x$ -ray applications simultaneously, glucose being given by the mouth to avert any toxic symptoms. The next bout of fever was abortive after an interval of thirty-eight days, and one other attack, after fifty-two days, was the last the patient had had. Since January, 1923, he had been hard at work, retaining his weight. A third series of neokharsivan injections and  $x$ -ray treatment was given early in 1923, although the symptoms had all disappeared. The second case was also of the Pel-Ebstein type, but the pyrexia was not so sharply marked off, the rises of temperature being more gradual and the falls more irregular. This patient, a man aged 41, was admitted to St. Bartholomew's Hospital with symptoms and signs suggesting a subphrenic abscess. An operation revealed nothing abnormal in the abdomen, and it was particularly noted that the spleen appeared to be quite normal. In view of the curious rises of temperature and an  $x$ -ray discovery of enlarged glands in the thorax, the patient was given a course of  $x$  rays and later a combined course of neokharsivan and  $x$ -ray treatment. The patient left the hospital apparently cured, but returned a year later with similar symptoms, which responded to the same treatment as before, and the patient had been back at his work for some considerable time. In the general consideration of the treatment of these conditions Sir Thomas Horder thought that several questions arose. In the cases he had described, was the arsenic or the  $x$  rays responsible for the favourable results? He thought the  $x$  rays were of greater value, but that probably a combination of the two forms of treatment was desirable, if not essential, in cases of this type. If both were desirable, what was the best method of combination? He thought synchronization was most efficacious. With regard to dosage, arsenic must be used boldly and the question of liver damage must be settled for each individual case; the best route for the arsenic was the intravenous. The dosage of  $x$  rays he left to subsequent speakers, and while he had had no experience of radium in the Pel-Ebstein type of case, he had treated nodal cases of lymphadenoma with radium with marked benefit. He referred briefly to other forms of treatment which had been used in this disease.

Dr. ROBERT KNOX described the treatment by  $x$  rays of the first case referred to by Sir Thomas Horder. At first he had used slightly filtered rays over a large area of skin, but when it became obvious that a lengthy treatment was required he had advised that the filters and the voltage should be increased so as to prevent damage to the skin and to reach the deeper structures. Discussing  $x$ -ray treatment of lymphadenoma in general, Dr. Knox described the surprisingly rapid disappearance of swellings followed by a period of apparent cure, after which a relapse followed.  $X$  rays gradually seemed to lose their effect until finally a relapse occurred where the swellings would not respond to treatment, and a fatal termination was not long delayed.  $X$  rays gave the best results in glandular and mediastinal growths, and radium if deeper structures were involved. He considered that the dosage of  $x$  rays should not be excessive. Small doses at short intervals over a long period gave the best results, and this treatment should be continued for some considerable time after an apparent cure had been obtained. He thought that the control of this disease by radiations was probably due to some biochemical action through the blood stream; hence he believed that simultaneous injections of arsenic were of great value. Cases must be observed very carefully during treatment, and close collaboration between the clinician and the radiologist was of the greatest importance.

Dr. F. PARKES WEBER emphasized that one of the fundamental problems in lymphadenoma was diagnosis. The pathology of the condition had been carefully worked out, and he considered that statistics as to the disease were urgently needed. These statistics should show the grounds on which diagnosis had been made and the nature of the treatment adopted. He criticized the diagnosis in both the cases reported by Sir Thomas Horder. In the first case there were no enlarged glands anywhere, and in the second case the spleen was normal and the only enlarged glands

were those radiologically detected in the thorax. Dr. Weber referred to certain had effects sometimes produced by radiation treatment where, although local swellings decreased in size, the general condition of the patient became much worse, and often a fatal termination rapidly ensued.

Dr. A. S. MacNALLY reported two cases of lymphadenoma where beneficial results had been obtained by the use of arsenic in the form of Fowler's solution. One case was still quite well after four years. In his opinion x-ray treatment did not seem to have any permanent beneficial effect.

Dr. J. H. DOUGLAS WEBSTER agreed that diagnosis was vitally important. He recorded some cases where tuberculosis and lymphadenoma existed in the same patient, and one case with a rather indefinite pathological condition, a gland removed during life proving later to be lymphosarcoma. He suggested that it would be very interesting to try the effect of x-ray treatment during the febrile attacks, for certain observers had reported that radiations had more effect at higher temperatures. He reported one case treated with both radium and x-rays; while radium produced quicker results, relapses occurred at shorter intervals.

Sir THOMAS HORDEN, in reply, expressed surprise that any doubt should be thrown upon the nature of the disease in the cases he had described. At autopsies on similar cases where glandular enlargement had also been absent quite definite changes had been found in the liver characteristic of Hodgkin's disease. All stages of the disease existed between simple local glandular enlargements and cases such as he had described. There were, in fact, many lymphadenomata, and he considered the results of the treatment he had described of value, since a new discovery with regard to treatment of uncommon cases often led to improved methods of treatment of the more common varieties.

## TETANY.

A MEETING of the Royal Medico-Chirurgical Society of Glasgow was held on January 26th, the Vice-President, Mr. JOHN PATRICK, in the chair.

Professor LEONARD FINDLAY in opening a discussion on tetany recalled briefly some of the outstanding events in the history of the disease. Although convulsions during the dentition period had been known to Hippocrates and Galen, it was only at the beginning of last century that tetany was first appreciated as a distinct entity when Clarke, in 1815, devoted a chapter of his book *Commentaries on Some of the Most Important Diseases of Children* to "a peculiar species of convulsion in infant children." In 1860 Trousseau once more described the three signs of carpopedal spasm, laryngismus stridulus, and convulsions as manifestations of one disease. In 1874 Erb described the increased electrical excitability, and in 1876 Chvostek noted the increased mechanical excitability of the peripheral nerves, both of which phenomena were of great value in detecting the latent stage of the disease. Professor Findlay then referred to the various hypotheses as to the pathogenesis of the disease and to the relationship of idiopathic tetany to tetania parathyreopriva. He concluded by describing the investigations of Professor Paton and himself which had led them to the adoption of the guanidin intoxication hypothesis.

Dr. STANLEY GRAHAM then discussed briefly the main theories regarding the etiology of tetany as suggested by various workers from a study of the blood chemistry. The four main hypotheses held at present were: (1) guanidin intoxication, (2) disturbance of the ratio of sodium and potassium to calcium and magnesium, (3) calcium deficiency, and (4) alkalosis. With regard to the guanidin intoxication hypothesis, he was of the opinion that until more accurate methods for the estimation of guanidin were devised little further confirmation could be obtained. The action of sodium and potassium as irritative salts and of calcium and magnesium as sedative salts had been known for many years, and it had been suggested by several workers that a relative increase of the irritative or decrease of the sedative salts in the blood would account for the

increase in the excitability of muscle. He considered that though theoretically such disturbance of the ratio could be responsible for an increase in electrical excitability of the muscle, it seemed to play very little part, if any, in the production of tetany, as seen clinically. The association of a diminished calcium content in the serum with certain forms of tetany he had found to be by no means constant, and in two recent cases of active tetany the calcium content had been normal. Also in other forms of tetany—gastric and hyperpnœic—the calcium content might be normal. In uræmia with a low calcium content no instance of tetany had been recorded. The disappearance of the signs of tetany after the administration of calcium chloride, supposed to be due to the supply of calcium ions, was now considered to be due to the acidosis produced. Ammonium chloride had been found to be as effective as the calcium salt, while calcium lactate failed to relieve the tetany. The acidosis of a gastro-enteritis had been found to cause the signs of tetany to disappear. Dr. Graham concluded by discussing the alkalosis hypothesis in its relation to the various types of tetany, and showed that while it was greatly concerned as a factor in all the types of tetany it was unlikely to be a causative factor. A toxic factor in the presence of an alkalosis might account for many of the symptoms, but such hypotheses at present lacked substantial confirmation, and the part played by the phosphorus was also deserving of further investigation.

In the unavoidable absence of Dr. GRACE H. ANDERSON, Professor Findlay read her contribution on the treatment of infantile tetany. Some of the earlier methods of treatment were first described and the reasons for their failure discussed. Dr. Anderson then went on to describe the mode of administration of calcium chloride adopted by her. In the active stage, with the three cardinal symptoms present, it was best to give the drug in 30-grain doses every four hours till all symptoms had disappeared. It was found that the urgent symptoms disappeared after one or two doses, but the latent signs took two or three days to vanish. In the latent stage of the disease smaller doses could be given and continued over a longer period. The drug was well tolerated by infants, though the disagreeable taste made the tablet form preferable in older children. Dr. Anderson concluded by referring to the treatment of tetany by ultra-violet radiation.

In the discussion which followed Dr. G. H. CLARK agreed that some form of intoxication was responsible for tetany, with probably an alkalosis as an important or even determining factor. He found it difficult, however, to support Dr. Findlay in blaming the parathyroid gland for idiopathic tetany, and believed the cause to be gastro-intestinal. He thought it unlikely that a disease showing practically the same symptoms in adults and in children should have a parathyroid origin in the latter and not in the former, and no one suggested that parathyroid disease was the cause of tetany in cases of dilated stomach, cholera, or enteric fever. Diseases of endocrine origin were uncommon and not readily amenable to treatment, whereas idiopathic tetany was by no means uncommon and was fairly readily cured. Dr. Clark then referred to a case of true parathyroid disease which had yielded to the administration of dried parathyroid extract.

Dr. ADAM referred to the treatment of a large number of cases of laryngismus stridulus. He compared this condition with asthma of the larynx, and mentioned the toxæmic factor associated with asthma. He had found also in spasmophilic children an eosinophilia similar to that in toxæmia. He referred also to the importance of diet in the treatment and to the part played by carbohydrate excess.

## Deep X-ray Therapy.

Dr. JAMES R. RIDDELL described briefly a series of five cases of malignant disease of the throat and mouth which had been treated by deep x-ray therapy. Two of the patients were shown to the society.

1. Epithelioma of the lower jaw and gum—confirmed by pathological report—treated with three doses of x-rays by the Erlangen method over a period of five months. No recurrence since healing took place eighteen months ago.
2. Tumour of left vocal cord, clinically malignant, treated by two doses. Had remained well for twenty months.

which originally appeared in *Biometrika* and is a fine example of pure biometry. The second part deals with various aspects of vital statistics, and includes a demographic study of the American peoples, which is an admirable piece of work. The third part contains various studies of medico-statistical problems, and includes a witty and provocative paper on the statistical evaluation of public health activities. We will not refrain from quoting the concluding paragraphs.

"May I close with an illustration which may serve as a warning of the dangers of the statistical method? In 1881, before the diphtheria bacillus had been discovered, there appeared in one of the leading medical journals of Germany, by an author of standing, a paper apparently proving, or at least making apparently highly probable, the conclusion that the eating of potatoes was the cause of diphtheria! It was shown, by conventional statistical reasoning, that the disease first appeared in Europe near the close of the 16th century; that it appeared *after* potatoes were introduced as an article of diet; that the disease had increased concomitantly with, and at about the same rate as the increase in the consumption of potatoes as food; that the most severe epidemics of diphtheria occurred at the time of the planting and the harvesting of potatoes; children from 2 to 3 years of age were particularly attacked because they played with the potatoes at the time of sowing and harvesting, while the older children were in schools; in one region, Schmalkalden, diphtheria was rarer than in another, Malstatt-Burbach, otherwise similar, because in the former place potatoes were bought in small quantities and immediately consumed, while in the latter place large quantities were laid in, and the people came more often in contact with spoiled potatoes. Now the point I wish to make about this tale, which seems so weird and ridiculous, now that we know what causes diphtheria, is that the statistical reasoning in the paper cited is every bit as good and cogent as at least much of the statistical work in the field of public health in this country at the present time. We may be, and I fear too often actually are, making just as egregious spectacles of ourselves in our statistical discussions of tuberculosis, infant mortality, etc., as was the gentleman who proved (?) that potatoes cause diphtheria. I hope that the moral of this true story is plain."

Probably some infidel when he reads the following sentence in Professor Pearl's study of influenza—

"But the outstanding *single* factor, which apparently more than any other one thing yet discovered, determined how abruptly or explosively the mortality was to rise at the outbreak of the epidemic, was the normal death rate in the community from organic diseases of the heart!"

will mutter "potatoes"; indeed, the sentence is not happily worded, but Professor Pearl knows the difference between correlation and causation, and anyone who reads the whole of his papers on influenza should know it too.

The fourth part of the book deals with statistics of population, discussing and illustrating the use of the logistic curve, which was the topic of Mr. Uday Yule's recent address to the Royal Statistical Society.

The volume should be read, not merely by statisticians, but by all medical men, particularly by public health workers. Of course there are many points open to criticism; there are in any good book. But Professor Pearl writes so clearly and so temperately that in his most polemical moments he probably hurts fewer sensibilities than the average statistician wounds when he thinks he is being especially polite.

#### MODERN METHODS IN HEART DISEASE.

The general practitioner must look askance at the appearance of any new book on heart disease, feeling that he will find in it a terminology which he cannot quite understand. In Dr. HEATHERLEY's book on *Modern Methods in the Diagnosis and Treatment of Heart Disease* he will find information supplied in a very practical manner, interspersed with crisp illustrations and without the aid of any graphic records. The author admits that he was brought up in the tenets of the old school and became converted to the new after twenty-five years of general practice, and the book has been specially prepared for the use of general practitioners. It is not a textbook on heart disease, but it is full of useful advice. The various abnormalities of the heart beat are discussed in a way that will rivet attention, while the chapters on heart failure and angina pectoris should prove very helpful. The closing chapters deal with symptoms and signs in general and with prognosis and treatment. The author puts in a plea for the general

practitioner making use of his opportunities for original research, and points out that "neither a £300 electrocardiograph nor even a gilt stethoscope is required." There are very few points in which we would feel inclined to differ from the author, and none is sufficient to detract from the usefulness of the book as a whole. One can imagine the author's style gripping the reader, so that he will feel inclined to read steadily through the volume. The book has been specially dedicated to "those who find salvation in compensatory hypertrophy and who fear a well-conducted mitral."

This notice has been inadvertently delayed, and we understand that a second edition is now in the press.

#### THE ADDER.

So few people nowadays have opportunities of meeting with the elusive denizens of our wild places that to many the title of this notice may suggest a machine in a city bank or other commercial office, rather than the true subject of Mr. NORMAN MORRISON's monograph, which is at home on the sunny banks and rocky wilds of Great Britain. In *The Life-Story of the Adder* he has put on record the results of many years' patient study and experiment, and has produced a work which, as Sir THOMAS OLIVER writes in a foreword, "will rank as a classic upon one of the sub-orders of vipers."

As a contributor to the press under the pseudonym of "Ophidia" Mr. Morrison has for years been known as an authority on British serpents. In this book he tells all that is known of the nature and habits of the *Vipera berus*, including some discoveries of his own. By actual experiment he has ascertained that frogs and toads are immune to adder venom, but that eels and presumably other fish are susceptible, for an eel which was bitten by one of his adders became paralysed and died in five and a half hours.

Some savages on certain ceremonial occasions devour their totem animal. It was not with any superstitious feeling of this sort, but in order to make his knowledge of his subject as complete and intimate as possible, that Mr. Morrison once dined on a boiled adder. He says that it was by no means disagreeable to the palate, that the flavour was between fish and flesh, and that the meal did not disagree with him.

It is well known that there are no indigenous snakes in Ireland, although two grass snakes were found in County Wicklow a few years ago. It is less well known, perhaps, that the island of Iona alone among the Scottish islands has no snakes, although they are common in the much larger island of Mull only one and a half miles off. Mr. Morrison does not attribute the immunity of Iona to the influence of St. Columba, but to its geological history. To test the *genius loci*, he took an adder from Mull and gave it a run (if such a word may be used of a snake) in Iona, which it seemed to enjoy, and it apparently felt no ill after-effects, although it was sent to Edinburgh packed in Iona grass. He also quotes Dr. Leighton as authority for the statement that an adder has been known to swim from Mull to Iona. Unfortunately this interesting would-be colonist died shortly after landing, its death being "probably due to heart failure," but it is obviously open to believers in the legend to attribute its decease to Columba's curse.

To the question whether adders swallow their young to protect them from danger Mr. Morrison can give no certain answer, for although one of his captives brought forth seven young vipers, they were prematurely born and she took no further notice of them.

Mr. Morrison fears that adders may become scarce in the West of Scotland. There seems no reason to think that this is the case in the South and West of England, for it is considered dangerous for children and dogs to wander in certain rocky places in Cornwall on account of the number of vipers. It might be a pity were they to become extinct in Britain, for their friends assert that they do more good by killing vermin than harm by occasionally biting

\* *Modern Methods in the Diagnosis and Treatment of Heart Disease.* By Francis Heatherley, M.B., B.S.Lond., F.R.C.S. London: Baillière, Tindall and Cox, 1923. (Demy 8vo, pp. x + 203. 5s. net.)

\* *The Life-Story of the Adder.* By Norman Morrison, F.Z.S.Scot., Campbelltown. With foreword by Sir Thomas Oliver. Paisley: Alexander Gardner, Ltd.; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd. 1924. (Cr. 8vo, pp. 133 + 14 figures. 6s. net.)

a dog or human being. Mr. Morrison found a full-grown rat in the stomach of an adder; such a large animal could hardly be captured by the non-poisonous grass-snake, yet the adder, though smaller, is able to do so, thanks to its deadly venom, which owes its power to its haemolytic property. Mr. Morrison suggests that this property might make adder venom of value in the treatment of cancer, but it is not to be expected that its action could be restricted to cancer cells only.

The adder is untamable and when in captivity invariably starts a hunger strike and dies of starvation. Even when she (four-fifths of the adders found are females) is forcibly fed she refuses to digest the food and dies just as soon and as surely.

Lord Avebury believed that he had won the affections of a she-wasp and described in moving words her dying farewell to him. Mr. Norman Morrison is under no delusion as to the possibility of making a friend of an adder, but he evidently has a very soft spot in his heart for these "charming creatures," as he calls them, and his enthusiasm for his subject much enhances the interest and value of his book.

#### APPENDICITIS AND ALLIED CONDITIONS.

THE importance of the early recognition of acute appendicitis and the necessity for prompt surgical intervention are now universally recognized. Dr. GUILLAUME does not challenge the wisdom of this; but in his book, *Les Colotyphlites*,<sup>1</sup> he contends that appendicitis has assumed too prominent a place in the diagnosis of abdominal trouble, especially of chronic abdominal trouble, of which he considers the appendix is often unfairly held to be the cause. The work is dedicated to the memory of Professor G. Dieulafoy, whose views the author shares, and to whose clinical sagacity and diagnostic acumen the author, in his introduction, pays a striking tribute.

The history of the progress of our knowledge of abdominal diagnosis is reviewed. Before the days of the widespread recognition of appendicitis, perityphlitis held the diagnostic field; and now, in the author's opinion, the pendulum has swung too far in the other direction, and many conditions are labelled appendicitis whose real nature is an infection, not really of the appendix, but of adjacent parts of the intestinal canal. Pain in the right iliac fossa is the almost constant feature of these disorders, and a considerable part of the book is devoted to a careful investigation of the significance of this syndrome. Dr. Guillaume urges his readers to investigate the part played in the production of these phenomena by a variety of affections and so to arrive at a proper understanding of the real nature of each and the appropriate treatment.

The book is divided into fifteen chapters, followed by an epitome of the author's conclusions. The bibliography is extensive, containing more than a thousand references. Drawing on a wealth of anatomical and physiological facts, Dr. Guillaume studies the various problems presented; these include the factors tending to produce appendicular mischief, the relation of appendicitis to other morbid conditions affecting the intestines, and the problems presented by chronic appendicular trouble and the signs pointing to its presence. Abnormalities, both of the structure and the position of the ascending colon, are discussed, as also the unduly mobile caecum and its relation to chronic intestinal stasis.

Dr. Guillaume is careful to define the terms he uses to designate such conditions as typhlocolitis and colotyphlitis. Typhlocolitis is the condition found in those false appendicitis cases of intestinal origin so named by Dieulafoy. Under the heading of colotyphlitis numerous affections of the intestinal tract are brought together and analysed; they are then considered synthetically and their relationship with the signs and symptoms referable to the right iliac fossa described.

The author is to be congratulated on having written so interesting and challenging a book. The problems that have engaged his attention are of wide interest, and his contribution to the subject undoubtedly throws much light on

the etiology, diagnosis, and treatment of those chronic abdominal troubles whose features resemble appendicitis so closely.

#### A MEDICAL MISSIONARY'S REMINISCENCES.

THERE must be few men in this or any other country who are university graduates alike in arts, medicine, divinity, and law, as is J. E. Hine, Bishop Suffragan of Grantham, and formerly Bishop successively of Likoma, Zanzibar, and Northern Rhodesia. That a man with these qualifications should have devoted many years of his working life to missionary service for the Church of England in Central Africa is an arresting fact, and now, under the title of *Days Gone By*,<sup>2</sup> Bishop HINE has written his autobiography. The story embraces his medical training at University College, with notes on his teachers and contemporaries; also his life at Oxford in the days of Burdon-Sanderson, including the scene in the Sheldonian, when the proposal to establish a physiological laboratory was carried after a keen discussion, which centred in the introduction of experiments on living animals. The author tells how Burdon-Sanderson developed a serious illness, and insisted on the future bishop attending him, a task by no means easy, as the patient looked on himself in the light of an experiment, and subjected the experimenter to a perpetual viva voce examination in all the symptoms and every step in the treatment.

But the great bulk of Bishop Hine's fine volume consists of a detailed account of his labours in Central Africa after taking holy orders. His dispensary and surgical work is only incidentally mentioned, his heart and soul being wrapped up in the establishment of Christianity. Central Africa, he urges, can never be a white man's country; while malaria and sleeping sickness may be done away with, the tropical sun remains, and it is of great importance to the welfare of the world that, in addition to teaching the native races to till their land, rule by law, and exercise justice, they should be brought under the strengthening discipline of the Christian faith. To that end Bishop Hine has devoted himself throughout a life spent in the midst of the discomforts and dangers and diseases belonging to such a country. Now he is back again in his own land, still engaged in his congenial work, but yet finding leisure to write this interesting autobiography.

#### NOTES ON BOOKS.

A REPORT of the eleventh Congress of Medicine of the Northern Countries, held at Christiania,<sup>3</sup> has lately been published by Dr. OLAF SCHEEL as a supplement to the *Acta Medica Scandinavica*. Professor P. F. Holst, in his preliminary address to the congress, recalled that in the previous congress held twenty-five years ago at Christiania the main subject of discussion was organotherapy. On the present occasion endocrinology was considered in detail, and the great advance in knowledge during the twenty-five years between the congresses was apparent. The report contains two addresses—one on the treatment of thyroid diseases, by I. Holmgren, and another on metabolic conditions of thyroid origin, by H. C. Hagedorn. Besides these addresses fifty contributions are included in the report, each being in the language used by the author; in several cases the discussions following the papers are also briefly reported.

In his *Elementary Morphology and Physiology*<sup>4</sup> Mr. WOODGER, reader in biology, University of London, has attempted to meet the special needs of a student who has later to go on to anatomy and physiology by giving him a comprehensive survey of the form and activities of living beings. He presupposes laboratory work, and has very little to say about plant morphology or physiology; hence the word "animal" should have appeared in the title. Not only is Mr. Woodger's survey broad, but it is philosophical; throughout the description of the driest morphological details there runs the conception of the necessity for interpretation. Particularly

<sup>1</sup> *Days Gone By: Being some Account of Past Years, chiefly in Central Africa*. By J. E. Hine, M.A.Oxon., M.D.Lond., Hon. D.D.Oxon., Hon. D.C.L.Durham, M.R.C.S. London: John Murray. 1924. (Demy 8vo, pp. xii + 313; 15 plates, 1 map. 15s. net.)

<sup>2</sup> *Rapports et Comptes Rendus du Onzième Congrès de Médecine des Pays du Nord Tenus à Kristiania le 3 au 5 Juillet, 1923*. Publié par le Dr. Olaf Scheel. *Acta Medica Scandinavica*, Supplementum VII. (Med. 8vo, pp. 376; illustrated.)

<sup>3</sup> *Elementary Morphology and Physiology for Medical Students*. By J. H. Woodger, B.Sc. London: Humphrey Milford, Oxford University Press. 1924. (Demy 8vo, pp. xx + 523; 255 figures. 12s. 6d. net.)

<sup>4</sup> *Les Colotyphlites et le syndrome de la fosse iliaque droite (appendicitis, périticéolite, colotyphlites)*. Par le Dr. A. C. Guillaume. Paris: Gaston Doin. 1924. (Roy. 8vo, pp. xx + 385. Fr. 35.)

valuable is the way in which the facts of embryology are introduced, for this branch of biology can be made dull beyond all imagining. The way in which the large subjects of evolution, heredity, and variation, with their subtopics of the germ-plasm and Mendelism, are handled shows that the author has a power of discriminating between facts and surmises. Some even of the arid facts of histology are illuminated by interesting speculation, as when it is suggested that membrane-bone is more "primitive" than bone formed in cartilage. As the scope of the work is so wide, Mr. Woodger could not logically avoid discussing the controversial overgreens of biology—the relations of mind to matter, intonctionism and parallelism, mechanism and vitalism, and animal behaviour in general. He has succeeded in making them the most arresting parts of his treatise. When describing the mode of attachment of the ovum to the uterine mucosa some reference should have been made to the recent important monograph by Professor J. H. Teicher of Glasgow University. The statement (p. 13) that weight for weight fats yield less energy than carbohydrates is not in harmony with the careful pronouncements which elsewhere characterize this book; they really yield more than twice as much. The many illustrations are generally excellent, a large number of them being original.

The fifth edition of Mracek's atlas of skin diseases<sup>12</sup> has been brought up to date by Dr. PAUL MULZER of Munich, who has succeeded Dr. A. Jesionek in the editorship of this well known manual. The principal change in the present edition consists in the replacement of some of the previous illustrations by better plates, some of which have been taken from Stein-Henning's book, and others from Professor Hoffmann's collection of wax models at Bonn.

The trial of Frederick Bywaters and Edith Thompson for the murder of Percy Thompson took place so recently that there is no need to dwell much on the circumstances which are recorded with such full detail in the volume which Mr. FISON YOUNG has edited for *Notable British Trials*.<sup>13</sup> Bywaters was a waiter or a landlady steward on a P. and O. steamer, 20 years of age. Mrs. Thompson was a bookkeeper and manageress to a wholesale milliner, aged 28, who lived on rather bad terms with her husband Percy in a house he had bought at Ilford. She appears to have committed adultery with Bywaters some time before the murder. Bywaters brutally stabbed Thomson to death in his wife's presence. They were both found guilty, sentenced to death, and hanged. Such are the bare facts. Neither of them showed much intelligence or forethought in planning the crime, and their subsequent behaviour and contradictory statements made the task of the prosecution easy. The case was entirely devoid of interest from a medical point of view. It is true that the female criminal probably made several unsuccessful attempts to murder her husband by administering broken glass and other substances, but no medico-legal problems were presented. Mr. Young, who is a well known journalist, uses all his skill in an attempt to invest this sordid case with a romantic interest and to make an unfortunate

of the woman. We are more inclined to think that the letters were "gush" than that Mr. Young's hyperbolic statement that they form "a series of the most remarkable letters that have ever been made public in modern times." Except for the frequent allusions to what were clearly attempts at murder, the letters appear to us to be of slight interest. The callous way in which these attempts seem to have been discussed, the levity with which the crime of murder was regarded, and the brutality of the final climax must shock all serious minded persons, the more so as it was not necessary to the realization of their guilty hopes of free indulgence of their passions.

## PREPARATIONS AND APPLIANCES.

### Antiseptic Surgical Spirit.

The difficulty in obtaining alcohol in a pure state is a cause of no less trouble to the many who use it otherwise than as a beverage than to that section of the population who only know it as a constituent of drink. The only form of duty-free alcohol recently available for surgical and nursing uses was one which had been rendered comparatively undrinkable by the addition of naphtha. Methylated spirit was serviceable for those purposes until lately, when the Board of Customs and Excise adopted the course of adding to it crude pyridine in order to render it wholly undrinkable. Such spirit cannot be applied to the skin owing to the toxic activity of the pyridine.<sup>1</sup>

<sup>1</sup> See *British Medical Journal*, December 27th, 1924, p. 1207.

It is creditable to the enterprise of certain firms of manufacturing druggists that they have sought, with the Board of Customs and Excise, for a relief from the difficulty. The Board has granted permission for the supply of a spirit for surgical use which has been denatured in accordance with an approved formula containing no pyridine. Messrs. Duncan, Flockhart and Co. of Edinburgh, and the British Drug Houses, Ltd., of London, have each undertaken to supply non-pyridinized methylated spirit. We have examined analytically samples of the spirit supplied by these firms. They are free from pyridine, and appear to be perfectly satisfactory for all the uses of methylated spirit. They become milky on dilution with water, and there appears to be no escape from that objection. The different spirits are rendered antiseptic each in accordance with the maker's formula.

### Curved Surgical Needles.

Mr. C. A. STINSON, honorary surgeon, Wolverhampton and Staffordshire General Hospital, writes: The needles shown in the accompanying sketch may be of interest. The chord from eye to point is  $\frac{3}{4}$  inches, the arc 6 inches. The section is that of the average large needle. They are made (a) in flat cross-section with cutting points, and (b) rounded in section and point for peritonum. In closing the abdomen, peritonum, etc., they possess the advantage of saving time by dispensing with the use of a needle-holder, yet giving a clear field when finger-held. They compel alertness in an assistant. They require long sutures. The needles are made by Messrs Charles Spencer of Redditch, and are sold by all instrument manufacturers.

## NEEDS OF SCOTTISH HOSPITALS.

(Continued from page 281.)

THE Committee appointed by the Scottish Board of Health to inquire into the inadequacy of the hospital services in Scotland completed its sittings last week. The Committee again met on February 2nd under the chairmanship of Lord MACKENZIE. The witnesses examined on that day included Sir Robert Philip, LL.D., Sir Harold Stiles, F.R.C.S., and Dr. J. S. Fraser.

SIR ROBERT PHILIP said he was satisfied that present conditions did not meet the demand, but the amount of inadequacy varied in different parts of the country. Among other things there was insufficient accommodation for cases of non-pulmonary tuberculosis, although he considered that the local health authorities, for the most part, were doing their best to make provision. He attributed the growing demand for hospital accommodation to a greater attention to preventive medicine, to the development of research in medicine, and also, it seemed to him, that the humour of the age was to enter institutions. There was no doubt that the standard of professional attainment was much better in this country than it used to be, and therefore much of what was regarded as calling for hospital treatment in the past might now be dealt with in the home. He thought that home nursing facilities might be extended with much advantage, and he thought that a system whereby nurses went from the hospital to patients might prove of great advantage. Cottage hospitals throughout the country would seem a natural form of relief, but there was need for more formal co-ordination between different institutions. Patients should be encouraged more than they were at present to pay for their own maintenance; and it seemed to him absurd that patients, who merely required surgical relief, should have their maintenance paid while they were in hospital. If this aspect were presented more definitely to patients at the commencement of their stay in hospital, a large number would probably refuse to accept free maintenance. It seemed to him that State grants might be made, not merely in times of emergency, but for erection and definite extension. It would certainly be fair to call upon the State to recognize the claims of the teaching hospitals, whatever the State might be disposed to do in regard to other hospitals. In reply to a question, Sir Robert Philip said that in any district where it was proved there had been a failure to provide adequate hospital accommodation, the local authority ought to step in both in regard to this and in regard to nursing services.

SIR HAROLD STILES indicated how he would propose to make the advantages of the Royal Infirmary of Edinburgh available in the surrounding districts. He thought that the secondary hospitals were capable of doing more work than they had hitherto done, and thus relieve pressure on the infirmary, provided that they were efficiently staffed. Many of these hospitals should be enlarged; and, in so far as surgery was concerned, the work should be undertaken by men who were pure surgeons and not general practitioners. He thought the minimum working size for such a hospital was 100 beds. Cottage hospitals should also be linked up with the larger hospitals. As to paying patients, he favoured separate blocks with a separate operating theatre and separate administration. He approved of the principle of subsidizing surgeons in certain places, if not in the teaching hospitals. He also saw no objection to the State meeting the needs of hospitals, and did not think that this would have the effect of checking voluntary support. If the enlargement of secondary hospitals, or, for example, the Edinburgh Infirmary, were necessary, it would be the primary affair of the State to provide the capital while the public supplied the money to run the institution, and if the State

provided the capital sum it would actually be an inducement to the public to contribute.

Dr. J. S. FRASER, surgeon in charge of the ear, nose, and throat department of Edinburgh Royal Infirmary, speaking from a précis which he had submitted to the Committee, said that something would be lost if the voluntary system were to go. The medical profession generally, he believed, was still against nationalization of hospitals. He believed, however, that the advantages of rate and State aid would far outweigh the disadvantages. He did not think that service could be given efficiently under the present system, although it was very pleasant to work under. The present system could be kept going from year to year, but it could not be extended. With regard to the Royal Infirmary of Edinburgh, he advocated a considerable extension of ground and property, and suggested that a large nursing home in the immediate neighbourhood should be acquired to form the nucleus of a nursing home annex which would be a wing for paying patients. He considered that a "follow-up system" was required to ascertain progress of patients after leaving hospital. Contrasting Scotland with America, he said that 80 per cent. of the population in this country came to the voluntary hospitals for surgical treatment, while the consultants were supported only by the remaining 20 per cent. In America the proportions were almost exactly reversed.

On February 3rd evidence was given by Dr. William Robertson, D.P.H., F.R.C.P., medical officer of health for Edinburgh, on a précis of evidence which he had already presented to the Committee. He dealt mainly with hospital provision from the preventive side, and thought that the present provision of hospitals for the isolation of infectious diseases was ample.

Dr. ROBERTSON said that the provision for infectious diseases differed in different areas. The generally accepted rate was one bed for every 1,000 of the population, which might be satisfactory in rural areas, but should be increased for cities to one bed for every 800 of the population. The medical inspection of school children, which it had been hoped might aid in stamping out infectious diseases, had not in experience borne out this hope. He was satisfied that the aim of present-day public health along the lines of producing artificial immunity among the younger population would give good results; and the reduction of disease would lessen the demands on infectious diseases hospitals. He thought that in future the demands on isolation hospitals would be less pressing than they were now. This pressure would be further relieved when the population of the larger centres were housed under better conditions than they were at present. This witness said he hoped that the pasteurization of milk and the possibility that now existed of putting on the market pasteurized milk at the same price as ordinary milk would have a considerable effect in diminishing diphtheria, scarlet fever, and tuberculosis. He thought there was a need for supplementary wards where, after having passed through the acute stage of measles and whooping-cough, patients might pass a period of convalescence and have fresh air treatment. These supplementary wards need not be of elaborate or substantial structure. At present during acute epidemics of these two infections the shortage of accommodation compelled them to discharge patients immediately after they had recovered from the acute stage. Another principle that might reasonably be considered was the setting aside of special wards for the treatment of scarlet fever and diphtheria where paying cases might be treated. With regard to the subject of tuberculosis, he held that the provision of institutions for this disease was unequal; and that the accommodation for advanced cases was insufficient, and patients often had to be sent out to a very unsatisfactory home in order to make room for other cases. Dissemination of tuberculosis could be actually traced when advanced cases were allowed to live and die in small houses. With regard to venereal diseases, Dr. Robertson expressed the opinion that there was not enough hospital accommodation. Much more preventive work could be carried out if additional beds were provided for the proper treatment of children affected by the disease. With regard to venereal disease the public health committee in Edinburgh was fully convinced that compulsory notification was the right policy. He thought that there were no insuperable difficulties in regard to co-operation between the voluntary, public health, and Poor Law hospitals, given good will on all sides.

Dr. J. H. MIELE, medical officer to the Edinburgh education authority, in giving evidence said that in Edinburgh they had two school clinics. So far as eye diseases were concerned, there was no co-operation between the education authority and the Royal Infirmary. The authority had no opportunities for operative treatment of tonsils and adenoids, and these cases went to the Royal Infirmary and elsewhere. He believed that if the education authority undertook this treatment a small hospital with beds would be necessary. In 1912 the education authority had made an agreement with the Royal Infirmary whereby the authority contributed a certain amount to get x-ray treatment done in that institution for ringworm, and this arrangement had been very successful.

Major G. STEVENSON, M.D., Glasgow, member of the Massage Board of Scotland, gave evidence in regard to the proper organization of this type of work, and said it might be possible to save beds in general hospitals and to shorten the period of incapacity after injury and prevent much chronic invalidism and crippling by this means. The position regarding massage training in Scotland at present was that there was only one school, situated in the Western Infirmary, Glasgow. Speaking generally, the numbers of workers trained in massage in other hospitals were hopelessly inadequate to cope with the numbers of patients requiring this treatment. The present tendency all over the country

was towards a radical change as regarded the position of massage departments of hospitals. Many patients were sent to hospital for the sole purpose of receiving treatment by massage. This affected both surgical and medical cases and both out-patients and in-patients. It was suggested that massage and medical electricity should be put at the disposal of any insured patients requiring it, and that more might be done in the way of forming local treatment centres in industrial areas. With regard to the group of children's cases, there was a possibility of group treatment; that is to say, that children suffering from similar conditions might be treated together in welfare centres and afterwards at school by methods such as re-education of muscles and artificial sunlight. As regarded the group of chronic invalids, many would be best treated in their own homes, and there might be a district masseuse service on the lines of the district nurse service. He thought it would be profitable also to have centres in mining districts where massage treatment could be obtained.

On February 4th the Committee examined Dr. Alexander Shearer, who is medical officer of the Scottish Board of Health, with regard to the medical service of the Highlands and Islands.

Dr. SHEARER explained that a sum of £42,000 was voted annually by Parliament and paid to the Highlands and Islands Medical Service Fund for the general purpose of providing forms of skilled assistance auxiliary to general medical service. The general idea was in bringing medical attendance within the reach of crofters and dependants of insured persons at fees which they could reasonably be expected to pay, despite the great distance of their residences from the nearest doctor. Close co-operation between authorities and voluntary agencies, such as district nursing associations and hospitals, was clearly contemplated. During the year 1924 grants had been paid to 64 nursing organizations, the number of hospitals assisted had been 6, and the number of ambulance committees 3. Towards the end of the year payments had been made for the first time towards the maintenance of resident surgeons in the islands of Shetland and Lewis. The witness said that, in addition to 155 nurses whose maintenance was assisted from the fund, a number of nurses were also supported by private persons. He thought that an addition of between thirty and forty nurses to the existing staff was required, as well as a more general provision of motor conveyances for the nurses. By the provision of motor-cycles two nurses might be able to cover an area for which three were at present necessary. The annual cost of a nurse, including salary, was between £180 and £200. This witness said that the number of beds available in the 22 hospitals of the Highlands and Islands might be taken as 340, and he thought this amount of general hospital accommodation was reasonably adequate, although he believed that some medical cases at present treated at home would be sent to hospital if they were certain that accommodation would always be available. He thought that by a service of specialists in cottage hospitals the flow of cases to the south would be stemmed to some extent. In certain remote localities there was a strong case for the provision of some form of hospice, which could conveniently take the form of a nurse's house having accommodation available for the reception of emergency cases. The sites at which these hospices should be erected would have to be the subject of special survey in regard to nursing needs, means of communication, etc. In regard to additional services, he thought that the services of medical consultants might be made available, and in the matter of surgery the need for specialist assistance was more urgent and would be heartily welcomed. An addition to the annual grant in aid would be required if progress in these matters was to be maintained. The witness agreed that it might in some instances be better to spend money on main roads so as to facilitate transport than to spend it on building new hospitals.

Mr. JAMES HAY, an Aberdeen advocate, gave evidence supplementary to statements which had already been made in regard to the Royal Infirmary of Aberdeen. This infirmary, he stated, had 309 beds, and a deficit on the working for last year of £749, as well as improvements on the x-ray department, etc., amounting to £2,449, had been met from legacies. He considered that the voluntary system had risen to the requirements of the North of Scotland in a wonderful way. Although the expenditure of the infirmary had increased enormously in recent years, income had kept pace with the increase. Amongst the sources of income were contributions from insurance and friendly societies, which last year amounted to £1,402. The directors of the institution thought that 400 beds would be ample accommodation in Aberdeen for many years to come. The witness was of opinion that the amounts of £360,000 capital outlay and additional revenue of £30,000 previously mentioned to the Committee by another witness as necessary for the joint hospital scheme in Aberdeen were greatly exaggerated. He suggested, however, as sources from which additional revenue might be got, the health insurance societies, a grant for surgical tuberculosis, and a Treasury grant under conditions similar to those given to universities. In the case of grants he would postulate no interference from the outside. The Chairman remarked that the information seemed to show that, although there was a shortage in Aberdeen itself, there appeared to be a surplus of accommodation in other places; and he asked whether by co-operation with other hospitals beds could not be cleared with greater rapidity. The answer was that that had not been considered. Witness did not know that there were any hospitals with vacant beds.

At the conclusion of the evidence submitted on February 4th the Committee sat privately to consider what additional measures should be taken by it to further its object.

The Committee then adjourned *sine die*.

## *Novus et Vetera.*

### DUELLING IN INDIA.

It is a curious fact that in an age when duelling prevailed no officer in the Indian Medical Service was ever killed in a duel, though at least six cases are on record in which officers of that service killed their antagonists in duels. In three of these cases the survivor was tried for murder in one or other of the Indian High Courts, and, almost as a matter of course, acquitted: in one case tried by court martial the accused was cashiered, but the penalty was subsequently remitted. In two cases, in both of which the duel was fought on foreign territory, no proceedings seem to have followed. In one case it is not stated what weapons were used; in the other five pistols were the arms selected. Duelling was common in India for about a century, and duels without a fatal result attracted little attention and were not recorded. The practice gradually died out before the Mutiny.

The earliest case recorded of a fatal duel, in which an Indian medical officer was concerned as principal, took place in 1777; the papers relating to the case are preserved in the Calcutta Record Office. Captain W. Crabh, officer commanding at Monghir, reported to Government, in a letter dated June 4th, 1777, that Surgeon James Ford had shot Lieutenant Sydney Smith in a duel. Ford was sent to Calcutta to stand his trial for murder in the Supreme Court. Procedure was slow. On December 4th, 1777, six months later, Robert Jarrett, the Company's attorney, was ordered to conduct Ford's prosecution. On December 27th Jarrett reported that Ford had been honourably acquitted. Ford had entered the Company's service in 1766, rose to be surgeon-major of a brigade in 1781, and died at Barhampur on April 6th, 1783. He served in the Rohilla war of 1774, and in the first Maratha war in 1781, as senior surgeon to Colonel Carnac's force.

The next case occurred some three years later, in or about 1780, and is mentioned in *Memoirs of William Hickey* (vol. i, p. 319). Surgeon Kenneth Murchison fought a duel with a Captain Crofts, at Lucknow, and shot Crofts dead. No proceedings seem to have been taken in this case. Lucknow was then the capital of the Kingdom of Oudh, independent territory. Murchison was an officer in the Bengal Army, but his services had been lent to the King of Oudh. Crofts had borne a commission in the British Army, but had resigned it, and was in the service of the King of Oudh, not in that of the Company. Probably the Government of India never heard of the case, officially; if they did, they would consider it no business of theirs. Murchison entered the Company's army in 1776, spent most of his service in Oudh, went home on furlough in January, 1784, did not rejoin, and was struck off from that date. He died at Bathampton in 1786. He was the father of Sir Roderick Murchison, the great geologist.

The *Calcutta Gazette*, which was then a newspaper, publishing general news as well as the official gazettes, in its issues of March 26th and April 30th, 1789, mentions that a duel had been fought at Pondicherry between Mr. W—y, of the Madras Civil Service, and Surgeon R—, of Madras, in which the former was shot through the head and the latter had his leg fractured. Mr. W—y was James Woolley, a civilian of high rank in the Madras Civil Service. It is not possible to identify Surgeon R—, for there were in 1789 no fewer than five officers of the Madras Medical Service of the rank of surgeon whose names began with R; among them was William Roxburgh the botanist; further, the official naturalist, Surgeon Patrick Russell, who resigned in February, 1789, may still have been in Madras in April. No criminal proceedings were taken, the duel having been fought on French territory. Evidently the two combatants had gone over the border

to Pondicherry to fight the duel, as Englishmen used to go to Bonlogne for the same purpose, after duelling had been stopped in England.

Surgeon William Betty, of the Madras Service, was tried by court martial and cashiered on October 6th, 1803, for having killed, on September 7th, 1802, Lieut.-Colonel Sir Robert Hamilton, of the Bengal Army, in a duel at Ambuyna, a small island in the Malay Archipelago, where they were present on military duty. Why Betty was tried by court martial, instead of being sent for trial by the Supreme Court, is not quite clear, but Ambuyna was not British territory; it was therefore not within the jurisdiction of the Indian courts, and both Hamilton and Betty were there on military duty. Exactly the same facts, both as to duty and locality, apply, however, to the next case, which was tried in Calcutta. The order of court, quoted below, suggests that the court martial was rather for other breaches of military duty than for the duel itself. Two years later Betty was restored to the service by the Court of Directors, by an order dated April 18th, 1805, in which they state:

"We have been influenced in our decision upon Mr. Betty's case by the peculiar circumstances of his long arrest previous to his trial, and of his having been acquitted of all the charges brought against him, except that of breaking his arrest, in which he appears to have acted more from an error in judgment than intentional disobedience, and likewise by the very strong and unanimous recommendation of the court martial in his favour."

From this order it seems that Betty must have been acquitted of the more serious charges and convicted only of a more or less technical offence. Presumably Hamilton was the aggressor and challenger.

Assistant Surgeon Walter Key, of the Bombay Service, medical officer of the Company's cruiser *Malabar*, was tried in the Calcutta Supreme Court on January 13th, 1815, for having killed Lieutenant Passmore of the same vessel, in a duel fought on February 22nd, 1814, on the island of Bourro, one of the Moluccas. Lieutenant Edward Searight, who was first lieutenant of the *Malabar* at the time of the duel, but had succeeded to the command before the trial, was also indicted, having been Passmore's second. Lieutenant Irwin, who seconded Key, was not brought to trial. The chief evidence was that of Searight, who stated that Passmore had been the aggressor. Both prisoners were acquitted. Key was ill at the time of the trial, and died a few days later.

The sixth and last case is also the most interesting. On July 18th, 1835, Assistant Surgeon John Porter Malcolmson, of the Bombay Service, in a duel at Poona, shot and killed Captain Alexander Urquhart, of the Bombay Cavalry. Mrs. Malcolmson appears to have been the cause of the duel. *Nulla fere causa est, in qua non femina litet moverit*. This is the only one of the six cases in which any suggestion as to the cause of the duel has survived. Malcolmson was wounded in the hand, and got tetanus but recovered. After the duel Assistant Surgeon James Don was called to attend him. On September 25th, 1835, the survivor, Malcolmson, the two seconds, Captain Foster Stalken and Lieutenant James MacDonnell, and Don, were tried for murder in the Bombay Supreme Court, before the Chief Justice, Sir Herbert Compton, and Sir John Awdry, puisne judge. The prisoners made no defence. When Sir John Awdry began to deliver the charge to the jury, the foreman stated that the jury had made up their minds to acquit all the prisoners. The judges accepted this verdict, Awdry remarking that Don, who had not been present at the duel, but was called in after it was over, should not have been put on trial. Malcolmson had joined the army in 1825, and died at Nasirabad on June 16th, 1854. He served at the capture of Aden in 1840, and in the Punjab war in 1848-49, when he was present at the siege and capture of Multan and at the battle of Gujrat. Don took the L.R.C.P. Lond. in 1824, and was the first officer to enter the L.M.S. with this qualification. He joined in 1825, became a member of the Medical Board in 1855, retired in 1857, and died at Brechin on July 18th, 1864. He served in the first Afghan war in 1839.

## THE POSITION OF PATHOLOGY.

IN an article published on January 31st (p. 225) we gave some account of the quinquennial review contained in the report of the Medical Research Council for 1924, but omitted reference to certain important paragraphs relating to pathology and bacteriology. It is observed in the report that "The position and progress of these sciences, on which so much of the current work of medicine depends, cannot be regarded as satisfactory." This statement comes rather as a surprise after reading of the healthy condition of the sciences of physiology, biochemistry, and of experimental and clinical medicine. We took some natural pride in the achievements of the faithful stewards who have multiplied their talents, but must turn now to those from whom less has been received than was expected.

It should be said at once that the report criticizes the subjects of pathology and bacteriology only from the point of view of organization, but other critics have suggested that these sciences are now "sterile," and that further exploration is unlikely to lead to any new discoveries of value to medicine. The report does not take that attitude, and scattered throughout its pages is to be found abundant evidence that the sciences of pathology and bacteriology are attracting extremely able research workers from whose studies much is anticipated. Undoubtedly we have passed beyond the era of periodic sensational discoveries of microbes; we have reached, perhaps, the time for firm consolidation of territory won by brilliant and almost too rapid advance. Bacteriology is exemplifying the law of diminishing returns, but is far from being "played out." If it has come upon evil days it is not because of exhaustion of its vitality, but because of harmful external influences such as those which this report indicts with severity.

After tracing the historical development of the sciences of pathology and bacteriology, the report points out that "the practical value of bacteriology in the public health services and in medical diagnosis became obvious and the need for it became increasingly urgent at a time when in many places the university professor and his department were the only source of supply. At the same time the universities, all poorly endowed, were actually unable to equip these new subjects without exploiting this economic value of bacteriology and using the fees earned by the professor to support him and his department." Thus it happened that practically all the departments of bacteriology, in the English universities at least, have been developed as commercial laboratories. Similar evils have existed in the big hospitals, where full advantage has not been taken of the unique opportunities for original investigations which exist because the pathologist has been commonly so poorly paid that he has found it necessary, and indeed has been expected, "to augment his salary by making paid routine examinations for his colleagues in practice or by taking the remunerative path of vaccine therapy."

The Medical Research Council's report deplores the fact that during the past five years little improvement in the general situation has taken place. In former

days, when the laboratories of the universities were performing a task which could not have been done adequately elsewhere, it was possible to offer some defence for this commercial system, but those days have passed, since a sufficient number of competent bacteriologists could be found outside the ranks of university teachers for the work required by local authorities and private practitioners. How their work might be organized and their status upheld has been very ably indicated in what is commonly known as the Dawson Report.<sup>1</sup> That report suggested that at certain primary centres there should be laboratories, of which the first and essential function would be the provision of facilities for general practitioners to make such examinations as they could and wished to do. Assuming such help in recording results as is elsewhere indicated through secondary centres, university centres, and the Medical Research Council, the result of this organized union of clinical observation and pathological research would be, it was believed, to make large additions to our knowledge, especially of the early stages of disease. The stereoscopic view produced by the combination of the visual fields of clinician and pathologist brings often into relief essential factors in a case which would otherwise escape observation. Experimental work may not infrequently be sterilized if divorced from clinical work, the problems being tackled *in vitro* rather than *in vivo*. Although specialism remains necessary in the more recondite parts of the subject, yet the giving back of pathology in part to the general practitioner would result in a triple line of advance. Research pathologists in university centres and elsewhere would be supplied with more material, thanks to the increased number of collectors working for them in wider fields; general practitioners would handle personally a most valuable weapon in diagnosis; and, thirdly, provision would be made for collecting, collating, and publishing that knowledge which at present too often dies with the individual.

Another problem of very great importance presents itself in this connexion. The setting free of the universities and other research laboratories from the drudgery of routine work implies an increasing infliction of this necessary, but often soul-destroying, labour upon a group in the profession for whom no prospects of anything higher are at present discernible. These routine workers, engaged in the same dreary round of simple investigations year after year, find their intellectual outlook cramped, and inevitably become mechanical in their work. Without prospects of promotion to more advantageous positions or to appointments conferring facilities for original investigations, their services are lost to scientific research. It is neither good nor necessary for pathological and bacteriological work to be penalized in this way. The problem is to a certain extent considered in the Dawson Report, in which it is suggested that those who work at the primary laboratory centres might spend occasional periods at the laboratories of the secondary centres for the improvement of their skill and knowledge. It is further hinted that the secondary centre laboratories should be linked up with the chief, or university, centres, which would deal with problems of exceptional difficulty, or investigations involving very special or expensive inquiry. Something more than this is necessary, however—namely, the possibility of the specialist workers passing from one grade to a higher in accordance with their increasing

<sup>1</sup> Consultative Council on Medical and Allied Services. Interim Report on the Future Provision of Medical and Allied Services. 1920. London: H.M. Stationery Office. Cmd. 693. Price 1s. net. See Section VI (a), pp. 18-20.

knowledge and ability. This would be attained by the creation of a graded service, comparable with other national services, in which promotion would be the reward of ability. Junior members of such a service would receive a thorough training in technique, and would be encouraged to use their talents rather than neglect them, as is the inevitable result at present under the daily pressure of performing simple investigations which soon become mechanical. As they became expert their services would be made available in more advanced researches: proved ability would bring with it escape from routine and the provision of increased opportunities for original work. This would produce a number of trained investigators who would interest themselves in the many problems of which the solution is at present delayed.

The report of the Medical Research Council points out that further assistance in the advance of pathology may be legitimately expected from the universities and medical schools. Unfortunately, many universities are still reluctant or unable to relieve their staff from the monotony of routine examinations, for their departments have been built up on a basis of commercial work, and so the financial difficulties in the way of reform appear almost insuperable. At Oxford and Cambridge, however, the schools of pathology have now been relieved of such commercial work, and rewards have come in the shape of generous benefactions. Thus, at Oxford the Dunn Trustees, and at Cambridge the Rockefeller Foundation and Mr. Ernest Gates, have provided large sums for the erection and equipping of new buildings for pathological studies. As the result of this a strong forward movement may be confidently expected at these two universities, and it may be noted in passing that pathology has already been included amongst the subjects for the advanced honours course in natural science at Cambridge, where also college fellowships have been given for the subject. As Lord Curzon points out in the report, the community at large will be well served by an increase in the number of those enabled to lead the active intellectual life of research and higher teaching, thus opening the only certain channel for rapid gains even from the utilitarian standpoint.

### PERPENDICULAR HOUSING.

A PROBLEM, suddenly acute in Birmingham, and casting its shadows before in London, has arisen out of proposals in both cities to undertake slum clearance schemes by the provision of large blocks of workmen's flats in central districts. The thorny aspects of the Birmingham problem revealed themselves at a recent meeting of the City Council, when a noisy and acrimonious discussion was provoked by the announcement of a programme for the demolition of a slum area and the replacement of back-to-back houses and other insanitary dwellings by what is described as an experimental block of flats. There is a difference of opinion on this policy between two committees of the council. The Public Works Committee recommends the expedient as a partial solution of the housing problem, whereas the Health Committee complains that it is a retrograde step and subversive of the interests of public health. The Health Committee is supported in its attitude by a letter written by Dr. John Robertson, medical officer of health for Birmingham, deprecating strongly the recommendation, and this letter the committee circulated among the members of the council, thereby bringing a good deal of criticism both upon itself and upon Dr. Robertson.

We do not propose to discuss the propriety of the Health Committee's action or that of the medical officer of health; but the general question as to whether it is advisable or not in these days of housing reform to erect blocks of tenement dwellings in congested areas for artisan tenants and their families is clearly one on which those responsible for or interested in the health of the community are entitled to express an opinion. A letter by Mr. Christopher Martin, consulting surgeon to the Birmingham and Midland Hospital for Women, which has also been published in the course of this Birmingham controversy, argues that small children living in such buildings are apt to be cooped up out of the sun and fresh air, and consequently to incur a serious risk of rickets. Dr. Robertson, in his letter, also expressed the opinion that the general result of life in flats is that young children suffer from very ill defined ailments and are definitely more susceptible to the influences which predispose to rickets than those who live in detached cottages. It is perhaps unnecessary to labour the point, so well recognized by all authorities on hygiene and sanitation, that, *ceteris paribus*, the prevalence of rickets is in inverse proportion to the opportunities which the children have for the enjoyment of sunlight and fresh air, and that infective disease has an incidence almost in direct proportion to the degree of congestion and the number of inhabitants to the acre. The troubles of overcrowding may be mitigated by piling dwellings one on top of the other, but they are not removed. For this reason it is to be hoped that the authorities of Birmingham—the home of progressive and resourceful municipal policy—will find a better solution of this difficult problem than to carry into effect the recent resolution instructing the Public Works Committee to proceed with the erection of this experimental block of flats. An amendment—that no family with children under 6 years of age should be accommodated on the upper floors—was incorporated in the resolution. A notice has been given to rescind the resolution, which, with the incorporated amendment, was passed amid some confusion, with the result that certain members of the council were not fully aware of what was taking place. We hope it will not be said of Birmingham, of all places, that it is building houses not fit for children to live in.

The London scheme, which was announced at the meeting of the London County Council this week, provides for the clearance of a slum area in St. Paneras, to the north of Euston Road, and the rehousing of the dispossessed persons in five blocks of flats, nine stories high. Colonel Levita, chairman of the Housing Committee, brought forward the proposal, but at this stage the committee makes no observations on its practicability so far as the provision of blocks of flats is concerned. It is stated that in any event the proposal is not intended to supersede existing methods of housing, but merely to offer a supplemental method for limited use on housing sites in central areas. The buildings, if the scheme goes forward, will be somewhat after the fashion of American city tenements, with light steel framing and concrete panels, and will provide nearly 600 flats. The amenities proposed include quick-running lifts, central heating and hot-water supply, with an open fireplace in each flat in addition to the radiators, dust shoots in every lobby, a direct lighting supply to every room, and through ventilation. Each flat would have a balcony where a baby could sleep in the open air, and on each block there is to be a roof playground. The buildings would be set back to a distance of forty feet from the present

roadways, so that the rooms on the lower floors would not be overshadowed. The proposal came in for some criticism at the meeting of the London County Council, but it received a greater measure of commendation, and one or two of the Labour members supported the idea. Colonel Levita said that he had long been aiming at high buildings. Such a nine-story building was within the limits of the Housing Acts, and he considered that these higher edifices were a weapon wherewith the problem of London housing might be attacked, and that St. Pancras was a place where the experiment might very well start. The Council agreed to spend £150,000 in dealing with this area of St. Pancras (which is known as the Ossulston Street area), including provision on the site for nearly all the 2,700 persons who will be displaced; but the proposal for the nine-story buildings, which is still in the realm of suggestion, is to have further consideration before it is adopted.

Whether the amenities in the London scheme can silence similar objections to those which have been urged against the Birmingham scheme is a matter which will have to be carefully considered when the proposals materialize. In the discussion in the Birmingham City Council it was stated that in Liverpool large blocks of eight-story flats are contemplated, and that Liverpool has been encouraged in such expedients by the success which has attended the provision of flats, of a less ambitious kind, in that city as a solution of the housing problem.

#### IODINE PROPHYLAXIS AND GOITRE.

Last week we drew attention in these columns to the increasing use of iodized salt for the prevention of goitre, bringing our notice to an end on a somewhat diminuendo note. For it has seemed that the precise part played by iodine in regard to goitre prevention is not yet understood; that it is not clear that all endemic goitres are of the same order or due to the same cause; that there is little agreement as to the amount of iodine required to prevent simple goitre; and that its prevention seems to be a domestic problem for each country. Thus we hear of brilliant results from America and Switzerland, but in New Zealand they do not seem to be of the same order. The New Zealand observations are of the greatest interest because of the careful control which was exercised by Professor C. E. Hercus and Dr. E. S. Barker.<sup>1</sup> They excluded all bias by "taking pains not to know" at the various examinations which of the children had received iodine and which had not. The observations relate to Waimataitai School in Timaru, where 467 children were under observation for six months, and to the Christchurch schools, where 1,514 children were under observation for one year. In the former the system decided upon was to give 2 grams (31 grains) of potassium iodide a year to all children irrespective of age. After six months' treatment, during which time 20 (out of the 31) grains of potassium iodide were administered, the following results were obtained: the thyroid increased in size in 5.7 per cent. of normal children who received iodine; it increased in size in 4.8 per cent. of normal children who received no iodine. In previously goitrous children the results were of a like order: the goitre increased in size in 6.2 per cent. of those who received iodine, in 6.1 per cent. of those who received no iodine. So far as this school was concerned it does not appear that the prophylactic use of iodine influenced the incidence of goitre one way or the other. At the Christchurch schools the results are more encouraging. Sodium iodide was used in this case: children aged 11

and upwards were given 120 grains a year; those aged 8 to 11, 60 grains; those aged 5 to 8, 40 grains a year. The method of dosage adopted was to give a weekly dose for ten weeks in each term (of 4 grains, 2 grains, and 1½ grains respectively) in half an ounce of water. The results were these: the thyroid gland increased in size, during the fifty-two weeks of the experiment, in 55 per cent. of normal children who received no iodine, and in 39.6 per cent. of children who received iodine. In children previously goitrous the goitre increased in size in 43.5 per cent. of those who received no iodine, and in 21.4 per cent. of those who received iodine. In this group of schools, therefore, the prophylactic use of iodine for a period of one year reduced the incidence of freshly acquired thyroid swellings from 55 to 39.6 per cent. The fact appears to be significant that, despite the use of sodium iodide, 39.6 per cent. of children developed goitre, and that if iodine want is to be regarded as the essential cause of goitre its absorption at the intestinal threshold is a question of the first importance. It is significant also that among the school children of Christchurch the administration of iodine for a period of nine weeks was as effective as its administration for fifty-two. Thus, among normal children the results observed were as follows: nine weeks' treatment, 38.5 per cent. showed an increase in size of the thyroid; thirty-eight weeks' treatment, 39 per cent. showed an increase in size of the thyroid; and fifty-two weeks' treatment, 40.5 per cent. showed an increase in size of the thyroid. As to existing goitres, the observers noted that 15.4 per cent. of untreated cases at the Christchurch schools decreased in size, as compared with 35.4 per cent. receiving iodine. But in this note we are dealing with the prevention of goitre, not with its cure. This admirable piece of adequately controlled work by Hercus and Barker is one that should be repeated by skilled observers in a number of selected schools in this country before any further attempt is made to introduce a generalized system of iodine prophylaxis. For we would repeat that the goitre problem seems to be a domestic one for each locality in which goitre prevails.

#### THE OPIUM CONFERENCES AT GENEVA.

THE joint committee of sixteen which was instructed to endeavour to find a way out of the deadlock in which the two opium conferences at Geneva had become involved failed to find an acceptable formula, and on February 6th the American delegation withdrew from the conference. The Chinese delegate has also retired in consequence of the attitude assumed by the American delegation. Lord Cecil, on behalf of the British delegation, deplored the attitude taken up by Mr. Porter on behalf of the United States; he said there was no difference of opinion that the ultimate object was to restrict the production of opium and the coca leaf to medical and scientific needs; but the most effective control at present was to regulate the manufacture of drugs, and the British delegation was disappointed that in the whole American memorandum there was only a passing reference to this. It was proposed to set up a central control board. They would have preferred that the United States should have continued to co-operate. They would, he added, have been stronger with them, but would continue the work without them. From the incomplete reports of the debates which have as yet been received it would appear that the actual or ostensible split occurred over the date from which, after a period of ten or fifteen years, the import or export of "prepared" opium for smoking should, in the words of the Convention of 1912, be "suppressed" or "prohibited." The American and Chinese delegations desired that the date from which the period would run should be the present time. Lord Cecil, on the other hand, impressed with the extent of smuggling

<sup>1</sup> *New Zealand Med. Journ.*, xxii, p. 169.

from China and elsewhere to our Far Eastern dependencies, desired to make the fifteen years of grace run from an indefinite date, to be determined by the League of Nations, when satisfied that opium production in China had been so far curtailed as to remove the dangers of contraband import. It is reported from Delhi that the successful stand made by the British delegation at the Geneva conference against the American proposals is regarded with some satisfaction there. On the other hand, the Mahatma Gandhi is reported to have declared that "if the whole of the opium traffic were stopped to-day, and the sale restricted to medical use only, I know there would be no agitation against it worth the name. Furthermore, from the moral standpoint, there is no defence of the Indian opium policy." It is much to be regretted that the close of the Geneva conferences will, it is feared, leave the opium question in a more controversial state than it was at their inauguration. It is sincerely to be hoped that American co-operation, which was so helpful at Shanghai in 1909, and at the Hague in 1911-12, 1913, and 1914, may again be obtained in effecting that "suppression of the abuse of opium, morphine, and cocaine" which it was the object of the Convention of 1912 to achieve.

#### ANTIQUE MICROSCOPES.

THE celebrated collection of antique microscopes which was made by the late Sir Francis Crisp is to be sold by Messrs. Stevens, at King Street, Covent Garden, on February 17th, thus exemplifying the sad but common fate of nearly all private collections. Among the 371 lots in the catalogue there are many of great interest for their historical associations, their excellence of workmanship, or the beauty or quaintness of their design. In the seventeenth and the first half of the eighteenth centuries microscopes were not the severely practical utilitarian instruments with which we are familiar. The craftsman was not content with having done his best to turn out an optically efficient instrument. He further lavished his time and skill in ornamenting every available part of the apparatus, whether the microscope were a tiny simple hand microscope, such as that made in Augsburg in 1686, and represented in the illustrated catalogue as Lot 10, or the elaborate compound microscope nearly two feet high which furnishes the frontispiece. This microscope, which was made by Adams of Fleet Street about 1746, is of silver and most elaborately ornamented, so much so that, with its Corinthian column and allegorical figures, it looks more like a presentation centrepiece than a scientific instrument. There are several other interesting specimens by this maker in the catalogue which show the excellence of his work. An earlier English maker was J. Marshall of Ludgate Street (circa 1704), whose skill is well represented by several examples, such as Lot 118. In his microscopes the body or optical tube was generally covered with ornamented vellum or leather, and the mounts were of turned wood such as lignum vitae. Lot 132, of which a full-page illustration is given, is of twofold interest—firstly, because of the beautiful inlaid box base on which the compound microscope stands and in which it is to be packed, and secondly, because it was the property of Pope Benedict XIV, and bears the triple crown and the crossed keys in marquetry on its case. This Pope was elected in 1740, but whether he had any serious interest in science we know not. The perfect condition of the microscope and case and the completeness of the fittings suggest that they were not much or often used. Lot 255 is an extraordinary Dutch instrument, having a conical body two feet in length and a field lens five inches in diameter. This Brodwingian microscope is probably unique, but the same may be said of several other lots. Among the solar microscopes is one of which the body tube is supported

by the uplifted arms of a carved allegorical figure, and another giant having a body twenty-four inches long and seven in diameter; only two instruments of the type are known; the other is in the Science Museum at South Kensington. There is such a wealth of interesting objects in this collection that it is difficult to do justice to them in one visit, and we wish that the auctioneers had found it possible to allow them to be viewed for more than one day and a few hours. We advise all those who are interested in the history of microscopy or in skilled workmanship to visit the collection on Monday next, February 16th, or before 11.30 on the day of sale, February 17th.

#### LEAD GLAZES IN COOKING UTENSILS.

FOR many years in this country leadless glaze has been employed for the earthenware manufactured for culinary purposes, but latterly there has been an increasing importation from abroad of casseroles, dishes, and similar articles in which a glaze with a high-lead content is used. Representations to this effect having been made to the Ministry of Health, an inquiry was ordered as to the solubility of this glaze during cooking operations. An account of this investigation, made by Dr. Monier-Williams, chemist in the foods division of the Ministry, has now been published. Having tested the action of citric acid solutions and of various foodstuffs upon a number of these vessels, Dr. Monier-Williams reports that, while there is no serious risk of lead poisoning resulting from their ordinary use in cooking, yet under certain conditions—for example, prolonged use with foods of a high degree of acidity—excessive quantities of lead may be dissolved from the glaze. Apart from this it was not possible to trace any connexion between the acidity of the foodstuffs and the amount of lead taken up. Dr. Monier-Williams does not consider that there is any valid reason why lead should occur at all in glazes, since leadless glazes are used by the great majority of English manufacturers of cooking ware. He adds that in any case it is apparently a simple matter for the manufacturer to produce lead glazes which show a negligible solubility, even on prolonged heating with citric acid solution. Much of the ware, however, that is now imported from the Continent appears to be of a low standard in this respect, sufficient care not having been taken in the control of temperature and the duration of firing in the kiln. It was considered advisable to extend the inquiry to enamelled hollow-ware in view of an outbreak of lead poisoning in 1922, due to the storage of beer in enamelled tanks containing lead. Dr. Monier-Williams found that the danger of injurious substances being taken up in significant amounts by foodstuffs from ordinary enamelled ware was remote. In one instance, however, a considerable quantity of boric acid was dissolved from the enamel of a frying-pan by tomatoes which were grilled in it. He concludes that if acid foods were heated for a long time in vessels of this particular make considerable quantities of boric acid might be dissolved out from the enamel.

#### TISSUE CULTURE.

THE cultivation of animal tissues outside the body, after being for some years little more than a biological curiosity, is beginning to show its value as a serious instrument of investigation. Dr. Carrel, one of the pioneers of the method, gave an address on its bearing on pathological problems to the Section of Pathology and Bacteriology at the Annual Meeting of the British Medical Association at Bradford last year, which was published with illustrations in our issue of July 26th. He then described the methods employed, and observed that though they were still in

<sup>1</sup> Reports on Public Health and Medical Subjects, No. 29: *The Solubility of Glazes and Enamels used in Cooking Utensils*. By G. W. Monier-Williams, M.A., Ph.D., F.I.C. London: H.M. Stationery Office, 1923. Price 6d. net.

their infancy and very ernde, he foresaw that this mode of investigation would have an important bearing upon our understanding of pathological problems because it could reduce complex phenomena into simpler terms and bring to light some of their underlying principles. This method of investigation has been used in this country by several workers, and the President, Sir Charles Sherrington, communicated to the Royal Society on February 5th a paper by Dr. H. M. Carleton on the growth, phagocytosis, and other phenomena in tissue cultures of foetal and adult lung. The result of the investigation was to show that the invasion of the medium in a growing culture is the result of sheet-like epithelial outgrowth from the alveolar epithelium of cut alveoli; of radiating growth of fibroblasts from the connective tissue of the lung; and of "membrane formation," in which the cells of the cicatricial epithelium detach themselves from the implant. Organization of the cleft thus formed is effected by epithelial cells and fibroblasts. These three types of growth may coexist in the same culture. Within the implant there occurs a swelling up, and a detachment of, the alveolar epithelial cells. Mitoses are frequent in these, even in cultures of adult lung. Finally, the implant undergoes a fibroid transformation. A cicatricial epithelium, derived from that of the bronchi, grows over the cut edges of the implant. Sterile coal or carmine particles are actively phagocytosed by both foetal and adult lung *in vitro*. The alveolar epithelial cells are actively phagocytic, the dedifferentiated cells of the cicatricial epithelium less so.

#### INDIAN POPULATION PROBLEMS.

IN a paper read before the Royal Society of Arts (Indian Section) on February 6th, Mr. J. T. Marten, Census Commissioner for India, dealt with some of the problems which emerge from the statistical matter collected in the 1921 census of India. He said that India had a high birth rate, owing chiefly to the universality of marriage and the economic simplicity of living, and a correspondingly high death rate, including a large infant mortality. The difference between the birth and death rates was not greater than in many countries of Europe, and might perhaps be estimated at a normal of 7 or 8 per cent. in a decade. In India, as in every other country, the most prolific portion of the population was the lowest stratum. Of the fluctuating influences determining the periodical variations from the average, the most important, except the catastrophe of famine, was the effect of climate on health, and not any variations in the material conditions of the people. In the matter of housing, clothing, and diet the lowest strata of Indian people were probably not worse off than the slum population of Western towns. The dry years were, on the whole, the healthiest, though they were not usually years of economic prosperity. On the other hand, there appeared to be an intimate connexion between the quantity and distribution of the rainfall and the incidence of disease, such as malaria and dysentery. There was always, in an agricultural population, even among those near the subsistence limit, a considerable margin of resource which enabled them to resist in a remarkable way temporary stringency. Sir Edward A. Gait, K.C.S.I., a former Census Commissioner, who occupied the chair, said that when Mr. Marten estimated at 8 per cent. the normal decennial growth of the population due to the excess of births over deaths, he could not have meant that that was the rate of growth to be expected, for the average decennial increase in the five periods for which statistics were available was only half this figure. On three occasions the increase was  $1\frac{1}{2}$  per cent. or less, once it was  $9\frac{1}{2}$  per cent., and once  $6\frac{1}{2}$  per cent. What Mr. Marten no doubt meant was that 8 per cent. was the rate to be expected in a decade free from widespread famine and from exceptional

unhealthiness. Even so this statement required some qualification, for the rate of growth in any given period was largely dependent on the age distribution of the population, and this varied greatly from time to time. In a severe famine the mortality resulting from insufficient and unwholesome food occurred mainly among the very young and the very old, many of whom, in the ordinary course of events, would have died a few years later, while people in the prime of life were but little affected. Consequently the period after a famine was one of exceptionally rapid growth, a high birth rate being accompanied by a low death rate due to the premature disappearance of many of the bad lives. The terrible influenza epidemics of 1918-19, which swept away  $12\frac{1}{2}$  million of the population, had an equally disturbing effect on the age constitution, but in the opposite direction. This disease was specially fatal to persons in the prime of life, so that at the commencement of the current decade there was an unusually low proportion of married women at the reproductive ages. Sir Edward Gait doubted whether the census of 1931 would show a growth equal to Mr. Marten's "normal" figure. He agreed, however, with Mr. Marten's conclusion that, apart from exceptionally severe and widespread famine, periodical variations in the rate at which the population of India grew depended more on conditions directly affecting the health of the people than on the degree of agricultural prosperity. He added that in India there was no such thing as "birth control." The lowest stratum might have a slightly higher birth rate, but he thought this was neutralized by a higher infant mortality.

#### PRISON AND THE PRISONER.

THE report of the Prison Commissioners for 1923-24<sup>1</sup> affords ample material for reflection, and much for congratulation. Less and less satisfactory are found to be the old methods of exalting the purely punitive side of imprisonment, while ignoring the many opportunities which prison life might afford of training prisoners to direct their thoughts and activities into channels which would provide them later with a sane alternative to crime. The Commissioners intend to take full advantage of all opportunities of training and re-education, and the record of their efforts in this direction is encouraging. There are several impediments to progress. One is the presence in the prison population of a number of weak-minded individuals who are neither insane nor mentally deficient in the technical sense, but are unable to benefit by any such scheme of training as is proposed for the normal prisoner. It is intended to place these under the charge of a special staff so soon as this can be provided. There is also the question of the association of young men in prison with hardened offenders. This under present conditions cannot be wholly prevented, and the Commissioners urge the provision of a separate establishment for young prisoners to ensure complete separation and special training. Lastly, there is the difficulty occasioned by the presence of longer-term prisoners along with those who are serving only a short time. The presence of the latter interferes with the proper working of an efficient scheme of training. The Commissioners have begun to meet this difficulty by using Wakefield Prison for the training of longer-term prisoners to the exclusion of others; since the experiment was initiated there have been very few cases of recidivism amongst the 218 men discharged. It need not be feared that the sole intention of the Commissioners is to render the prisoner's lot a happy one. Their object is to fit him for his duties as a citizen when he comes to be discharged. "The means to this end are," it is said, "fairly long hours of hard and steady work at an occupation which shall, if possible, give such industrial training as will enable the offender to earn his living;

the removal of needless degradations, and the encouragement of self-respect. The prison day should be hard, but the object is not mere severity. It should be interesting, but the object is not to make it pleasant. The aim is to make a citizen by quickening and directing the activities of both mind and body." There can surely be no two minds about the essential wisdom of such a project, tempered as it is by sound practical considerations. Coincident with the introduction of these reforms, and presumably because of them, there is said to be a marked change in the attitude of the prisoners themselves. As witness to this are the remarks of the governor of Hull Prison. "The atmosphere is now such," he says, "that a troublesome prisoner, instead of receiving at least sympathy from other prisoners as formerly, must plainly see that they regard him as being a disgrace to the establishment." The Commissioners pay special tribute to the increasing care exercised by the courts in the investigation of the circumstances of offenders and the avoidance of unnecessary committal to prison. The more liberal use of probation is urged in cases of young first offenders. Of the numerous reports submitted to the Commissioners that of the medical officer of Birmingham Prison (Dr. M. Hamblin Smith) calls for special mention, on account of the attack therein made on the system of committing offenders to prison without consideration of their individual requirements. He considers that the main cause of past failures has been neglect to recognize in criminal conduct a definite mental abnormality. He would have the problem of the delinquent envisaged alongside the problems presented by other mentally abnormal persons, and would have the treatment of the offender regarded as essentially a psychological problem. It certainly cannot be denied that many crimes have an undoubted psycho-pathological basis. Examples that may be instanced are many cases of pilfering in young persons, and the commission of offences because of an unconscious feeling of guilt. Such abnormal motivation of criminal conduct is only discovered by the expert psychologist; and in so far as Dr. Hamblin Smith's criticism of present methods draws attention to the need of such experts in the courts, it is of particular service. It is a far cry from that, however, to the doctrine that all crime is a disease made manifest, and some degree of caution must be exercised in accepting the tenets of a school of thought whose propositions are dangerously akin to such doctrine.

#### FRENCH SPAS.

PROFESSOR ALBERT ROBIN, who has written a preface for an album of the spas of France compiled by a French medical committee, thinks it necessary to apologize for the elegance of the volume and the beauty of the photographs it contains, and to insist that it gives also accurate information sufficient to guide a doctor in selecting a place suitable for his patient. This is true, but Professor Robin's serious intentions will, in not a few instances, be imperilled at a first glance because many French spas are in very beautiful situations; such are Aix-les-Bains, Cauterets, Allervard, Eaux-Bonnes, and Uriège, to mention only a few. Even in the plains the architect and town planner have gone far to make up for scenic deficiencies, and to reconcile the invalid to spending his days in sunny gardens and umbrageous parks. Vichy, for instance, is an excellent place in which to be lazy during the intervals left between the strenuous and varied therapeutic devices it so lavishly provides. There is, indeed, for very many people a fascination not easy to define about a well appointed French spa, whether in the Vosges hills, among the Pyrenees, or in the plains. The patient is expected to be up betimes, but the serious business of the day is got over in the morning, and in the afternoon rigid discipline is so far relaxed that he can feel himself once more his own

master and indulge in such recreations as the state of his health permits. Owing mainly to the university vacation the French spas are most frequented in July and August. Professor Robin suggests that where possible the months of May and June, or September, should be chosen; the extremes of summer heat—which can be very considerable, not only in the plains, but in a southern mountain valley—are avoided, the doctors have more time at their disposal, and the hotels, being less crowded, are able to give more favourable terms to visitors. The pamphlet is issued in this country by the Office Français du Tourisme, 56, Haymarket, London, S.W.1, where full particulars of the qualities of each spa and the best way of reaching it can be obtained.

#### INFLUENZA.

LAST week the number of deaths from influenza in the great towns of England and Wales again increased, but less than in the previous week—namely, from 195 to 202, as compared with an increase from 142 to 195. London alone showed a greater rate of increase; the figures of the last three weeks were 36, 39, 48. Manchester was the only city other than London recording more than 10 deaths (18). Five others—Bury (5), Salford (7), Bolton (5), Burnley (5), and Leeds (6)—had 5 or more. There has been a further increase of notified pneumonia, particularly in London and the North, but the statistical indications do not make it probable that the present recrudescence will be very serious. While the mortality of this epidemic is not heavy, it is common knowledge that influenza has been extremely prevalent in many parts of the country during the past few weeks.

#### REX V. BATEMAN.

THE medical profession will, we doubt not, have learnt with a deep sense of relief that the Court of Criminal Appeal has allowed the appeal against the conviction and sentence of Dr. Percy Bateman, a medical practitioner of New Cross Road, London, who was found guilty on December 12th, at the Central Criminal Court, of the manslaughter of a woman patient, and sentenced to six months' imprisonment in the second division. An account of the trial appeared in the BRITISH MEDICAL JOURNAL of December 20th (p. 1179), and a full report of the application for leave to appeal in last week's issue (p. 285). This week we publish at page 334 a report of the proceedings in the Court of Criminal Appeal on February 9th and 10th. The case for the appellant was listened to with the closest attention by the three judges (the Lord Chief Justice, Mr. Justice Salter, and Mr. Justice Fraser), and Mr. Norman Birkett, K.C., in the course of his ably sustained argument, had the advantage of many illuminating questions and comments from the Bench. It will be seen that the Lord Chief Justice, at the conclusion of the case for Dr. Bateman and the reply for the Crown, said that the Court was of opinion that the appeal ought to be allowed and the conviction quashed, but that in view of the importance of some of the questions raised their lordships proposed to consider their judgement and to deliver it at a later date. In view of this we think that comment by us should go no further at the moment, beyond expressing satisfaction at the outcome of this most important and most distressing case.

WE are glad to learn that Dr. Herbert Jones, whose recent illness has caused his many friends some anxiety, is making satisfactory, though slow, progress towards complete recovery. Dr. Herbert Jones was president of the Society of Medical Officers of Health a few years ago, and president of the Section of Public Medicine and Industrial Diseases of the Annual Meeting of the British Medical Association at Bradford last year.

## THE NEW MISSING LINK.

BY

SIR ARTHUR KEITH, M.D., F.R.S.,

CONSERVATOR OF THE MUSEUM OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

PROFESSOR RAYMOND DART, whose discovery of a "missing link" in South Africa has fallen like a bombshell on anthropological Europe, is well known to British anatomists. He is one of the many young medical graduates of Sydney University whose minds were bent towards research in anatomy by Professor J. T. Wilson, before this distinguished anatomist left Australia for Cambridge. In post-graduate days Professor Dart worked at University College, London, with Professor Elliot Smith, at the Royal College of Surgeons, and in research laboratories of the United States. He went to Johannesburg some three years ago to occupy the chair of anatomy in the University of Witwatersrand. In South Africa he found an earnest band of investigators opening up unexpected chapters in the early history of man. Old river-beds were yielding a sequence of stone implements almost as ancient as those of Europe. The remains of a fossil man had been found at Boskop, and soon after Professor Dart's arrival other human remains were found deep in the floor of a rock shelter on the southern coast of Cape Colony. These were examined by Professor Dart, and found to be of the Boskop race. Then came the discovery of Rhodesian man in the bowels of a limestone kopje in Rhodesia—a much older and more primitive type than that of Boskop. And now comes an equally remarkable discovery which is largely due to the initiative and perspicuity of Professor Dart.

In November last a lady demonstrator brought him the fossil skull of a monkey—a baboon. It came from a limestone quarry situated at Taungs, eighty miles to the north of Kimberley. There the quarrymen had worked their way 200 feet into a limestone bluff which rises 50 feet above the dry veldt of the surrounding country. The monkey's skull was blasted from the rock. Finding that his colleague, Dr. R. B. Young, professor of geology, was going to Taungs, he asked him to inquire into the source of the fossil bones in the quarry. Dr. Young arrived at the quarry in time to receive a mass of material just blasted from the base of the working face of the quarry. He gathered the fragments, and handed them to Professor Dart on his return.

In the mass of limestone Professor Dart found a cast which had formed within the brain cavity of a skull, and from the adjoining block he chiselled out the forehead and complete facial parts which went with the brain cast. The blasting had shattered and de-

stroyed most of the cranial bones. From these fragments the discoverer reconstructed the being to which he has given the name *Australopithecus africanus*. So exact and clear are his drawings and his descriptions that those who have studied his preliminary account in *Nature* (February 7th, p. 195) have all the data placed at their disposal for coming to an independent opinion. Indeed, those who have charge of much larger collections of anthropoid and human skulls and brains than

were at the disposal of Professor Dart have a somewhat unfair advantage over him. But with all these disadvantages against him his main conclusions are certain to stand.

He speaks of this new being as a "man-ape," and as standing "between living anthropoids and man." These are his expressions, but when we examine his text we find him quite alive to the fact that the animal he has brought before the scientific world is a man-like ape or anthropoid. The size and convoluted pattern of its brain leaves one in no doubt of this matter. Many fossil fragments of higher anthropoid apes have been found on previous occasions, in Europe and India, but this is the first time we have seen the complete face of one of them. In this case, the animal is young; the first permanent molar teeth have cut and are coming into place; this happens in the gorilla and chimpanzee towards the end of the fourth year—two years earlier than in human children. The face in all its lineaments is that of an anthropoid; there are blended in it some

Norma facialis of *Australopithecus africanus* aligned on the Frankfurt horizontal. (Reproduced here by the courtesy of the Editors of *Nature* and of the *Illustrated London News*.)

features of the chimpanzee, others of the gorilla, and some which belong to neither. But of humanity there is no trace save in one respect—its jaws are smaller and its supraorbital ridges less developed than in a chimpanzee of a corresponding age. There is a reduction in jaw development, and such a reduction has certainly taken place in the evolution of man. Further, the milk canines are less pointed than are those of the young chimpanzee, and the interdental space in front of the upper canine is less.

In volume the brain of this new anthropoid is of the size we find in young gorillas, but its shape is different. In the brain of the gorilla the width is 82 per cent. or more of its length; the gorilla—and the same is true of the two other living anthropoids, the chimpanzee and orang—is round-brained. The gorilla is low-brained; its height is small compared with its length. *Australopithecus* is long-brained; from Professor Dart's measurements one infers that

the width was 71 per cent. of the length; the brain is compressed from side to side, and is high. Thus, amongst anthropoids, as amongst living races of mankind, we have long-heads or dolichocephals and round-heads or brachycephals. Earth pressure may compress a skull from side to side and thus alter the natural shape of the brain cavity, but one may be sure that Professor Dart was alive to this source of distortion and excluded it.

Thus we have made known to us a high anthropoid, one which is clearly related to chimpanzees and gorillas but differs from both, and in the points wherein it differs making some approach towards man. Its exact relation to the human phylum will be cleared up by its geological age. To have any claim to stand in or near the human line of descent it must be able to claim an early Miocene date at least.

All living anthropoid apes are confined to tropical jungles. The limestone bluff which served as a tomb for this new anthropoid child lies 2,000 miles from the haunts of the gorilla and chimpanzee. The first supposition one makes—and it is justified by what we know of Europe—is that the climate of South Africa has changed, and that the tropical belt had once spread over the arid deserts of Bechuanaland. Professor Dart, on the other hand, leans to the supposition that Australopithecus may have assumed the posture and habits which have become perfected in man, and was thus able to wander far beyond the jungle limits. We cannot be certain of posture until we find a bone of the lower limb. One cannot see any character in the skull which justifies the supposition of an erect posture.

Further evidence will make clear how this fossil skull, and numerous others belonging to monkeys of the baboon type, became embedded in the limestone cliff at Taungs. One infers that in these limestone cliffs caves had formed, and that they again, with a change in climate, became filled and obliterated by stalagmite forming on their floors and walls. Animals which had died in the cave would thus have their bones preserved as fossils. These caves may not be older than late Pliocene or earlier Pleistocene.

However this may prove to be, there can be no doubt of the high importance of Professor Dart's discovery. He has found and given an exact and full description of a new and high kind of anthropoid ape; it is not only a missing link but a very complete and important one, but it lies altogether at the anthropoid end of the chain which culminated in man. It is a discovery which places Professor Dart's name in the front rank of students of the evolution of man and anthropoid.

## France.

[FROM OUR OWN CORRESPONDENT.]

### Travelling.

The French have ceased to deserve a reputation for ignoring geography. At any rate, as regards the medical world, we have many opportunities of travelling, if it were but on account of the numerous congresses. But now Dr. Loir of Havre, a great believer in thalassotherapy, is inviting us to make sea trips so that we may preach to our patients from personal experience to do the same. For those of us who can find time to take a three weeks' holiday this would be a marvellous opportunity of touring round the Mediterranean, in congenial company, and of studying some scientific subjects. If our many schools are represented on board they are sure to have quite a good discussion on the ever new subject of *varicella*. An invitation perhaps even more tempting is extended to all medical men

—foreigners and French—by the Cie Transatlantique to visit Morocco and Algeria. Two tours have been organized: one leaving Bordeaux on March 30th for Casablanca and returning from Algiers so as to reach Marseilles on April 24th; the second, leaves Marseilles on April 18th and terminates in Bordeaux on May 14th. The travelling by land will be by motor car, and all places of interest are to be visited under expert guidance. Full information can be obtained from Dr. V. Gardette (3, rue Alexandre de Humboldt, Paris 14).

A striking novelty in Morocco is the aerial ambulance service for the French expeditionary corps. Some 1,500 patients have already been evacuated through the air with no mishap. In many cases the time saved was in the ratio of a minute to two hours—namely, a twelve minutes' flight would bring a wounded man to a comfortable and safe refuge which could not have been reached under twenty-four hours by land transport. One plan is to bring the patient to the surgeon, and another is to bring the surgeon to the patient. Therefore the *aero-chir*, which is nothing less than a flying operating theatre, has been brought into existence. Professor Tuffier was the first to use such an apparatus in Morocco when rendering first aid to a French officer. The demonstration has been so complete that a medical member of Parliament, M. Chassaing, has proposed that every part of France should be equipped so as to allow the rapid evacuation by air of urgent cases. Realization sometimes works quicker than imagination.

### Physician v. Physicist.

Modernization of methods was never better illustrated than at one of our medical *concours* in a provincial faculty. The subject of a written paper had been given to the candidates and they were secluded from the wide world, when the denn was called on the telephone and informed that one of them was communicating with the outside by means of wireless; should he call at such and such room he would certainly be edified. Incredible as it seemed, the fact proved true. Asked what he was doing with that microphone, a young man answered that he was "experimenting." He was informed that the nature of his experiments was sure to interest the magistrate and that in the meantime if he handed over his resignation from his present appointment it would certainly be accepted. So this young man will have to devote his capacities to some other branch of science than medicine. We suggest physics.

### The Fight against Tuberculosis.

The President of the Republic took the chair at the Sorbonne last week at the meeting of the committee of the various associations fighting tuberculosis. In our country, where the problem of natality is appallingly urgent, the question of protection of infants is of the utmost importance. Professor Calmette showed that preservation is obtained every time that infants are separated from an infected parent. His suggestion is to provide for the child as soon as possible after birth. The country is well armed for that purpose, and statistics prove that many lives are saved. Cruel as it may seem to have one's child taken by hygienists, still it is less cruel than to have it taken by meningitis. The education of the public has now progressed enough to make this understood and accepted. In the same spirit our first mountain sanatorium for heliotherapy has just been opened at Odeillo in the Pyrenees, at an altitude of 5,000 feet. It is open to children under the protection of a certain number of institutions, priority being given to war orphans.

### Bone Prothesis.

In the Necker Hospital amazing improvements are being carried out in osteoprotehesis. The way bone can be replaced by plated ebonite can only be believed by those who actually see the patients and the skiagrams. Dr. Robineau has been waiting to publish his results until a sufficient number of years should have elapsed to make them certain. At the International Congress of Military Medicine (Paris, April 20th to 25th) we may expect to hear a few startling papers. This congress, with its wide opportunities of visiting various parts of France, is proving quite a success, and we hope that our British comrades will not miss this opportunity. Lest we forget!

G. Monro.

## Ireland.

### HONORARY F.R.C.P.I. CONFERRED ON SIR HUMPHRY ROLLESTON.

SIR HUMPHRY ROLLESTON, Bt., K.C.B., President of the Royal College of Physicians of London, was on Saturday last admitted to the Honorary Fellowship of the Royal College of Physicians of Ireland. The function took place in the College Hall, Kildare Street, Dublin, in the presence of a large and distinguished gathering. The Governor-General, the Provost of Trinity College, and Lady Aberdeen attended. The President, Sir William Thompson, who presided, welcoming the visitors, said that the most valued of many highly prized heritages of the College was its option to confer its Honorary Fellowship, from time to time, on men who had distinguished themselves in the profession of medicine, the allied professions of science, literature, and the fine arts. This privilege had always been most jealously and meticulously guarded, and none but those outstanding in their professions had ever been admitted. In the case of Sir Humphry Rolleston the College had no hesitation in unanimously electing him to Honorary Fellowship. In his address conferring the honour the President said that the College had 3,200 on its rolls, and they felt honoured in adding to that number one so distinguished in the medical profession. They had all watched with interest, pleasure, and pride, Sir Humphry Rolleston's steady progress on the ladder of success to his present unassailably eminent position. They all earnestly prayed that the new Fellow would long be spared to enjoy not only the Honorary Fellowship of the College, but the many other distinctions and honours which had been so deservedly conferred on him. Sir Humphry Rolleston was then duly admitted to the Honorary Fellowship and signed the roll.

The new Fellow returned thanks for the honour conferred on him, and proceeded to read an address on individual links between the Colleges of London and Ireland. His admission as a Fellow of the Irish College was a tribute, he said, to the sister College in London. These two Colleges had the same ideals as their aim: their pharmacopoeias were on the same lines, and the Presidents of the Irish College had been members of the Decennial Committees for the nomenclature of diseases. In the eighty years from 1836 to 1916 it was of interest to know that no less than twenty-eight Fellows of the London College, including presidents, had been by courtesy admitted to the Fellowship of the Irish College. Although younger, the Irish College had done what the London College had not done—last year it had admitted a lady, Mrs. Mary Hearn, as a Fellow. The Irish College as far back as 1877 had taken the lead in admitting women as licentiates—an example not followed by the London College till 1909. In addition to their great founder, Dr. Stearne, the lecturer referred to many prominent men who had been connecting links between the two Colleges. Sir William Petty, one of the original thirteen members, had been described as one of the most remarkable figures in Irish life. He had served as Physician-General to the Army, and had undertaken the task of surveying the country for the purpose of distributing the lands. In the following century there were at least three distinguished Irish physicians who contributed to strengthening the ties between sister colleges. These were Sir Edward Barry, Dr. Anthony Pelham, and Dr. Thomas Brooke. Barry was born in Cork about 1689, and after practising there came to Dublin, where he quickly won a high reputation, which was enhanced by a very learned work which he published on *Consumption of the Lungs*. He was Physician-General to the Forces, and was elected M.P. for Charleville. Later he went to London, and was admitted a Fellow of the London College, as were his contemporaries, Pelham and Brooke.

Proposing a vote of thanks to the lecturer, Dr. Walter Smith, Father of the College, and ex-president, said the name of Rolleston required no adventitious illumination. Sir Humphry's father, George Rolleston, was a man of graceful character, and had won merit as a professor

at Oxford University. Sir Humphry Rolleston had made some notable contributions to medical literature. He had spread his activities in many directions, and had served his country in several capacities in peace and war. It was no wonder that numerous honours and distinctions should fall to his lot, including being gazetted Surgeon-Admiral of the Royal Navy, an unusual distinction for a physician. In addition to his other qualities he had a facile pen, and had written a very interesting and instructive book on *The Medical Aspects of Old Age*. Sir John Moore, who seconded the vote of thanks, said that Sir Humphry Rolleston's record was one of unparalleled service to humanity, and in particular to the soldiers and sailors of His Majesty's Forces, giving them the advantage of his knowledge and skill during the great war, when he was consulting physician to the Royal Navy. His admission to the Fellowship of the Royal College of Physicians of Ireland forged one more link in the golden chain which bound the two Colleges together. The vote of thanks was carried with acclamation, which Sir Humphry Rolleston acknowledged, and the proceedings terminated.

### THE ROYAL VICTORIA HOSPITAL, BELFAST.

Dr. R. Marshall delivered a very interesting address to the Belfast Medical Students' Association on February 4th. Professor Fullerton was in the chair, and many of the visiting staff were present. The lecturer gave a brief account of the first records of hospital and dispensary work, and referred more fully to the *History of the General Hospital*, by A. G. Malcolm, M.D., one of its physicians, published in 1851; he also quoted some of the figures from early annual reports; these showed the gradual and steady increase of operations, number of admissions, and general work of the institution. The name was changed from the General Hospital to the Royal Hospital, and then, when it migrated to its present site, to the Royal Victoria Hospital in 1903. It was impossible to mention all the benefactors—their number was too large—but members of the Donegall family were always to the fore; for its present building and equipment the hospital was deeply indebted to the late Lord Pirrie, and to its president, Lady Pirrie.

The members of the medical staff, the superintendent (Colonel Forrest), and the students joined in warm and appreciative thanks to Dr. Marshall; reminiscences of earlier days, often of an amusing and not strictly professional nature, were related.

### THE JUBILEE NURSES.

Lady Elizabeth Kenmare, president of the Queen Victoria Jubilee Institute for Nurses, in the course of a communication addressed to the press, states that recent appeals, first for the endowment fund of the Queen Victoria Jubilee Institute for Nurses, and, secondly, for the relief of the distress in the West carried out by the Jubilee nurses working under Lady Dudley's scheme, have created a confusion in the mind of the public. It is desired to make it clear that the joint work is carried out by two committees under one organization. Twenty-five Queen Victoria Jubilee Institute nurses are partially maintained by a fund raised by the late Rachel Lady Dudley. They are managed by a committee in Dublin, because in the isolated districts where they work there is no possibility of forming local committees of management or of raising funds. The supposition that there are two independent organizations is harmful to both, as the work is one and the same, only differing in the fact that twenty-five nurses are managed from Dublin and the others by local direction.

## England and Wales.

### MANCHESTER SANATORIUM.

MANCHESTER City Council has decided to proceed with the scheme for installing 210 beds for tuberculous children at its sanatorium at Abergele; a further addition of 336 beds is contemplated in the future. The sanatorium is placed in an estate of 355 acres, and the new buildings to accommodate children will be erected on a plateau separated by a narrow gorge from the main buildings of the sanatorium. A southerly aspect enables the full value of the morning sun

to be obtained, with protection from the heat of midday and the afternoon. The Manchester Education Committee will undertake the supervision of education and of the teaching staff for these children. At present there is only accommodation for ten children in a small cottage on the estate.

#### BLACKBURN HEALTH EXHIBITION.

The Publicity Committee of the County Borough of Blackburn has organized a health exhibition which opened on February 11th and will continue until the 21st. The exhibition is entirely educational, without any commercial side; it has been prepared by the Central Council for Infant and Child Welfare and the staffs of the borough departments, particularly those concerned with public health and cleansing. Daily lectures have been arranged and also visits to the hospitals, open-air schools, farms, welfare centres, and other institutions. In connexion with the exhibition a handbook has been published, describing its objectives and some of the schemes for improving the public health in Blackburn. Short descriptions, illustrated by photographs, are provided, and make it possible to appreciate the great extent and value of the work that is being carried on. An interesting table is supplied of the cost of the various activities, both actually and also expressed in terms of a penny rate. Another table illustrates the reduction in sickness and the death incidence during the last forty years. The great reduction in infant mortality since 1890 is shown by a striking chart; this ratio has been reduced to less than half, the reduction representing a saving of 221 infant lives each year. In connexion with the exhibition sermons will be preached in various churches, and health plays are being performed.

#### NEWCASTLE-UPON-TYNE.

##### *Plastic Surgery of the Face.*

Mr. H. D. Gillies, surgeon to the Queen's Hospital, Sidcup, recently gave an address to the members of the Newcastle-upon-Tyne and Northern Counties Medical Society in the Royal Victoria Infirmary, Newcastle. In introducing the lecturer the President, Dr. Charles, alluded to the high character of the work Mr. Gillies had done, which entitled him to be regarded as a surgeon-artist. Mr. Gillies, in an admirable address, illustrated by lantern slides and photographs, riveted the attention of his audience by the description of his operative methods, the originality of which was fully recognized. The first thing necessary in every case, he stated, was to make a diagnosis, for without it no adequate treatment was possible. On the screen he showed how he obtained large skin grafts from the abdominal wall, transplanted these to the arm, for example, and subsequently from the arm to the face. These "sausage grafts," so called from their shape and consistence, supply an excellent type of skin, as was seen in the case of a young woman to whom he had, practically speaking, given, externally, a new neck. From the lantern slides it was readily observable what wonderful results had been obtained by the transplantation of sausage and Thiersch pressure grafts to faces which had been rendered repellent as a consequence of shell wounds or burns. In the evening the lecturer was entertained to dinner in Tilley's rooms by the council of the society. Twenty sat down to dinner. The chair was occupied by Mr. Willan, and the vice-chair by Mr. T. A. Hindmarsh. After the loyal toast had been honoured, Sir Thomas Oliver proposed that of "Our Guest," and in doing so said he regarded it as a great privilege that as a physician he should have been called upon to propose the health of their distinguished visitor. During the war the speaker had visited the hospitals in Amiens and Paris, where he saw, and was impressed by, the plastic face surgery which the French and American surgeons were doing, but the address to which he had listened that afternoon, and the results achieved by the operator, made him feel proud of British surgery. He congratulated Mr. Gillies on the success he had already attained. It was a line of practice in which he was pre-eminent. The toast was received with musical honours. On the following afternoon, in one of the theatres of the Royal Victoria Infirmary, Mr. Gillies operated upon two patients, in one of whom he prepared an abdominal graft for the treatment of extensive ulceration of the skin over the tibia.

#### *Lectures on Citizenship.*

In the Church of the Divine Unity a course of Sunday evening lectures is being delivered, the title of the course being "The town we live in." Last Sunday the second lecture was given by Professor Harold Kerr, medical officer of health for the city, who chose for his subject "The city healthful." Dr. Kerr dealt with such subjects as the increased longevity of recent times, the reduction of infantile mortality rate, the marked improvement in the death rate of tuberculosis, and with slums and the public parks. The lecturer brought his address to a close by appealing to the people of Newcastle themselves, who must, if they wish to have a "city healthful," personally co-operate in order to attain that end.

#### LEICESTER ROYAL INFIRMARY.

The annual meeting of the governors and subscribers of Leicester Royal Infirmary was held on January 28th. Mr. H. Johnson, house-governor and secretary, in presenting the annual report, said that the new wing added to the hospital had been instrumental in reducing the waiting list of patients from several hundreds to less than one hundred. The admissions to the adult ward had increased from 4,143 in 1923 to 4,758; but the admissions to the children's hospital had decreased from 756 to 719. There had been an increase in the number of in-patients from 4,899 to 5,477. During the year the increase in attendances in consequence of accidents had risen from 83,512 to 89,426; accidents in the street, and in factories owing to their increased number, were becoming more numerous week by week. The governors had authorized the expenditure of approximately £5,000 for additions to the casualty department, which was erected about twenty-four years ago. It was expected that there would be a deficiency of about £9,000 on the year's working, the total expenditure being £74,000, as compared with £65,000 in the previous year, and the income being £64,160. The sum of £9,000 from special donations and legacies had been added to capital. It was evident that no less than £10,000 a year was needed in the way of new income, but the appeal that had been made for £100,000 was now approaching completion, £92,000 having already been received.

#### THE FREEMASONS' HOSPITAL.

The annual meeting of the Freemasons' Hospital and Nursing Home in Brompton Road, London, was held on January 28th, the chair being taken by Lord Marshall of Chipstead, Past Grand Warden. The chairman's report stated that during the previous year 481 patients had been admitted, as compared with 427 in the previous year; the number of operations had increased from 374 to 449. On several occasions the waiting list had been as high as forty. During the year £1,725 had been devoted to the assistance of 110 patients who were unable to pay the hospital fees. The board of management had decided to close the list of founding lodges. An extension of the hospital would soon be necessary, although only surgical cases were dealt with. Lord Marshall, in presenting the treasurer's report, appealed for further donations in view of the increased number of beds that had been provided. At the end of December the £120,000 required for the endowment fund had been secured, and the invested funds were now nearly £110,000, but the excess of expenditure over income during the year had amounted to £2,579.

#### CLEAN MILK.

The importance of clean milk is being more and more recognized alike by producers, purveyors, and consumers, with the result that apart from Government departments voluntary organizations are taking an active part in the movement for attainment of perfection in the provision of this article of primary importance to infant and general welfare. The council of the National Clean Milk Society has now issued a print of recommendations in respect of immediate future milk legislation. It urges that the Tuberculosis Order of 1914 should be reintroduced with an amendment relating to compensation for condemned and slaughtered animals, the point being that the amount paid to the owner should be limited to the sum received by the local authority for the value of the carcass. Also it advises

that the Acts of 1915 and 1922 be consolidated subject to certain amendments. Such designations of milk as "guaranteed," "nursery," and "invalid's" should, the society holds, be illegal, and only those should be allowed which are referred to in Milk (Special Designations) Orders; milk should be sold by imperial measure; a local authority should have power to prohibit the sale in its area of milk if it finds the public health "is or is likely to be endangered" thereby; pasteurized milk should be so described; centrally approved model milk regulations, including classification and bottling, should be adoptable by local authorities; in boroughs of over 50,000 inhabitants there should be power, with central consent, to require the pasteurizing of all milk other than "certified" or "Grade A (tuberculin tested)." Other recommendations relate to milk designations, bottle caps, inspection by local authorities, and regular reporting of the results of inspection to the Ministry of Health. It will be seen that the society has given much attention to the details of milk provision and sale, and no doubt in its turn the Ministry will give careful consideration to the advice of a body which specially devotes itself to the subject.

#### CENTRAL MIDWIVES BOARD.

At a meeting of the Central Midwives Board on February 5th, when Sir Francis Champneys was in the chair, the Standing Committee dealt with a letter from a county medical officer of health as to midwives who had not notified their intention to practise, with regard to the calling in of medical aid and other points connected therewith. A reply, drafted by the chairman, was approved. Information had been received from the institution at which, recently, nitric acid had been used in mistake for silver nitrate, stating that the use of nitric acid had been discontinued. Dr. Rhoda Hicks Butler Adamson was appointed to fill the vacancy, caused by the death of Dr. J. B. Hellier, as examiner at the Leeds Centre. It was reported that the representatives on the Board of the various bodies had been reappointed without any change. The next meeting will be held on March 5th.

#### PRESENTATION TO DR. WRIGHT HILL.

Dr. J. Wright Hill, who was recently presented with several gifts by his friends on the occasion of his retirement after thirty-eight years' medical practice, took a very active share in the administrative side of medical work. He was a member of the West Ham Panel Committee and chairman of the East Ham Panel Committee. He is at present the chairman of the Stratford Division of the British Medical Association. During the war, besides his very heavy clinical work, he served as chairman of the local branch of the British Red Cross Society, in consideration of which he was appointed a governor of Queen Mary's Hospital, Stratford. Dr. Hill is also a justice of the peace.

## Scotland.

#### ROYAL MEDICAL SOCIETY OF EDINBURGH.

The annual dinner of the Royal Medical Society of Edinburgh was held in the hall of the Royal College of Physicians on February 5th, Dr. T. Drummond Shiels, M.P., presiding over a company numbering about 120. The guest of the evening was Mr. Alexander Miles, M.D., F.R.C.S., and among those present were: Lord Provost Sir William Sleigh, Professor G. Lovell Gulland, P.R.C.P.Ed., Sir Harold Stiles, P.R.C.S.Ed., Sir Robert Philip, and Surgeon Commander P. L. Crosbie, R.N. The chairman, proposing the toast of the guest, said that on the roll of the guests at the annual dinners of the society there were many eminent names, and they were proud to add to that roll the name of Mr. Alexander Miles, who was not only a great surgeon but also a great teacher, which was even rarer. Mr. Miles, proposing the toast of the Royal Medical Society of Edinburgh, said that it was, and always had been, a students' society; the bulk

of its members were still undergraduates. It was true that a few remained in active membership for a year or two after graduation, but these were usually house-physicians and surgeons in the hospitals or assistants in the laboratories of the professors and lecturers. It was well authenticated that the society was founded in August, 1734, and that it was thus the oldest medical society in the kingdom. Its inception was due to six students, who, after spending a social evening together in a tavern, agreed to meet once a fortnight in their respective lodgings, where a dissertation in English or in Latin on some medical subject would be read by one of them and be discussed by the others. This band of six was soon joined by one whom they were always proud to count among the founders of the society—the celebrated William Cullen—who perhaps more than any other man served to make the foundations sure. At the time when the society was founded medical opinion was in a state of flux. Medical practice had for long been based on the doctrines of speculative philosophers, of whom Boerhaave of Leyden was the chief apostle. A new school directed by Hofmann sought to replace these abstract theories by knowledge based upon observed facts. Cullen was one of the leaders of this school; he exerted a powerful influence upon his fellow members, stimulating them to think and to observe for themselves, and to question on every point the voice of authority. That had always been, and still was, the spirit which pervaded the society. It was an interesting coincidence that they were meeting on the anniversary of his death 135 years ago. It was mainly through the influence of their society on the Edinburgh school that the doctrines of Hofmann and his experimental system triumphed eventually.

In 1737 the society drew up a constitution and adopted the name of the Medical Society. In 1778 it became incorporated under Royal Charter, and a hall was built in Surgeons' Square, where the members remained till 1852, when they acquired the present hall and offices in Melbourne Place. The society had one of the finest medical libraries in the country, containing well over 30,000 volumes. During the war years, however, its revenue suffered seriously, with the result that there was a curtailment of the books purchased for a series of years, and a large gap existed on the shelves of what was an otherwise complete library. Mr. Miles appealed to old members of the society who could spare any books published during these lean years to communicate with the curator of the library. The membership of the society included the names of many men who had made medical history in this country for nearly two centuries. Among its most distinguished members in medicine Mr. Miles mentioned Andrew Duncan, Richard Bright, Marshall Hall, Robert Christison, Douglas MacLagan, Byrom Bramwell. In surgery there were the Bells, Robert Liston, William Fergusson, James Syme, and—the greatest of all—Joseph Lister; whilst in obstetrics there were James Young Simpson, A. R. Simpson, and Halliday Croome. A great many of their members had also become distinguished outside medicine. Such were Mark Akenside, the poet; Oliver Goldsmith; Mungo Park, the explorer; Sir Henry Holland, the traveller; Sir Gilbert Blane, who introduced lime juice into the navy; Sir Charles Hastings, the founder of the British Medical Association; Robert Finlay; Thomas Addis Emmet, the Irish patriot; and Charles Darwin. The society was now an integral part and one of the most valuable assets of the medical school.

#### PROPOSED COLONY FOR THE FEEBLE-MINDED.

Lord Provost Sir William Sleigh presided at a public meeting held in the City Chambers, Edinburgh, on January 27th by the Edinburgh Women Citizens' Association, to further a scheme for the establishment in Scotland of an industrial colony for the permanent care of the feeble-minded. Lady Leslie Mackenzie, Chairman of the Scottish Council of Women Citizens' Associations, said that the several associations had come to the conclusion that the time was opportune for action. The word to be stressed was "permanent." It was true that school boards had power to establish special schools where children could be trained until the age of 16, but the feeble-minded remained children in mind no matter what age or size they reached, and it was calculated that somewhere between

two and three hundred left the special schools every year. The object of the proposed colony was to take permanent care of inmates at all ages, to give as much school work as was necessary, and to train the inmates for work with complete separation of the sexes and proper classification of faculty for work under skilled supervision. They aimed at establishing a type of institution which would become an interest and impetus to local authorities and others concerned in this serious social question. Professor G. M. Robertson, physician superintendent of the Royal Edinburgh Asylum, sent a letter expressing his cordial sympathy with the object which the association had in view; education during school years might, he said, do much to lighten the burden of the individual defective, but could not endow him with what Nature had denied—the capacity to carve his own destiny and hold his own in the face of manifold temptations. The defective, like a child, might have a highly developed imitative faculty which, unless carefully tended, was a source of infinite danger, not only to the defective himself, but to the community. Much of the good of school training was rapidly undone when the defective was turned out into the world to fend for himself; his fate there depended almost entirely on the environment in which he was placed. Many became a burden on the community, and by propagating their own kind kept open this social sore. Experiments had been conducted in America and England which clearly showed that the industrial colony afforded a real means of grappling with the problem, for in such a place the economic worth of the defective might be exploited to its maximum extent, while at the same time he was shielded from everything that in the outside world led to his breakdown. Sir Arthur Rose, Chairman of the Board of Control for Scotland, stated that it was really the duty of the State to attempt to solve this problem. The State before the war had recognized its responsibility and passed a useful Act which provided for the care of the mentally defective, but the war had intervened and the Treasury now set an embargo on local authorities putting the provisions of the Act into force. It had begun to lift the embargo, but only to a modified extent, although it was gratifying to notice that certain enlightened local authorities in Edinburgh, Glasgow, and Govan had been so impressed with the importance of the work that they were, on their own initiative, going ahead with its development. Still in Scotland, at the present time, the amount of provision being made for these cases was hopelessly inadequate. Dr. H. C. Marr, one of the Commissioners of the Board of Control, said that on the whole mental deficiency and mental disorders were distinguishable; and, while in regard to the latter purely hospital treatment was necessary for cure and amelioration, in regard to mental defect care and an educational system were required. Many children could not be educated in the schools that were available, and the consequence was that a large number of mentally defective persons were passing into a life of irregularity and crime. There were nine institutions for the care of mental defectives, and in these, as well as in private dwellings, there were now under supervision in Scotland over 2,000 mentally defective persons. Even if this accommodation was increased by 1,500, as was proposed, the Scottish provision for mental defectives would still be lamentably small, and there was urgent necessity for the scheme proposed by the Women Citizens' Associations. Lord Sands, in moving a resolution pledging the meeting to support the efforts of the Scottish Council of Women Citizens' Associations to establish in Scotland an industrial and farming colony for the permanent care of the feeble-minded and stating that there would be no difficulty in finding abundant material for such a colony. Mental defectives, after school life, lost a great deal of the benefit they had gained. Many of them led very unhappy lives, and were also the cause of unhappiness to others, of depression, anxiety, and humiliation. There were also many moral dangers in allowing them to be at large in the community, and segregation, he was sure, would make for their own happiness. Work was the great source of happiness, and they would all be taught trades and treated with sympathy, tenderness, and love. Mr. W. H. Mill, in seconding this resolution, stated that the number of mentally defective children of school age in

Scotland was said to be over 6,000; probably there were in reality between 7,000 and 8,000, of whom nearly 5,000 could be educated. The motion was cordially adopted and a vote of thanks was given to the Lord Provost for presiding.

#### CENTRAL MIDWIVES BOARD.

At the meeting of the Central Midwives Board for Scotland held for the election of office-bearers, Dr. James Haig Ferguson was unanimously re-elected chairman, Dr. Michael Dewar deputy chairman, and Sir Archibald Buchan-Hepburn, Bt., convener of the finance committee. The meeting appointed other committees and examiners, and approved the list of recognized institutions, with the teachers attached thereto, for the training of midwifery nurses.

#### CHALMERS HOSPITAL: ANNUAL REPORT.

The report by the Directors of the Chalmers Hospital, Edinburgh, shows that the number of patients treated in the wards during the year was 673 and the number of out-door patients 2,541. On the balance between the ordinary income and ordinary expenditure there was a deficit of £709 2s. 7d. and an extraordinary expenditure of £332 11s., which made a total excess of expenditure over income of £1,041 13s. 7d. For the current year the directors would require to use the whole free income of the trust for 1925, and they further sought authority to draw upon the funds of the trust to an extent not exceeding £600 if they should find it necessary to do so.

[The continuation of the evidence before the Committee appointed to inquire into the inadequacy of the hospital services in Scotland is printed at page 316.]

## Correspondence.

#### CANCER OF THE OESOPHAGUS.

SIR,—Dr. Hill is, of course, quite right in his opinion (January 31st, p. 238) that there is a stage in the tortuous cicatricial variety of malignant disease in the upper third of the oesophagus where it may be impossible to insert a tube. This was in my mind when I made the remark regarding gastrostomy, knowing well the difficulty sometimes encountered. There is a stage, however, in all such cases where the obstruction can be overcome, so that given this point the statement would still hold good. The moral is that advice should be sought earlier. With regard to the lower end, there are difficulties, as Dr. Hill points out, owing to the contraction of the diaphragm and the irregularity of the growth; moreover, there is the liability of the tube being rejected on vomiting. Nevertheless, a considerable number of such cases can be successfully managed by a short tube, and, if not, by a long one. I have recently had under my care a man who wore at intervals a short tube over a period of eighteen months, and Dr. Stebbing showed me a man who had retained a short tube for several weeks. As I pointed out some years ago, these lower end obstructions can usually be traversed by a condé bougie, or feeding tube when the straight variety cannot be passed. Once such a tube can be passed and retained for three or four days, then the thin-walled rubber tube carrying the silver wire suggested by Dr. Hill can easily be inserted and worn indefinitely.

Recent experience has certainly led me to the conclusion that these low obstructions are more amenable to relief by tube than I was at one time disposed to think.

Mr. Souttar has undoubtedly brought forward an additional and valuable aid in the treatment of cancer of the oesophagus. Further experience will give this variety of tube its right place. Its employment will be restricted to those who are familiar with the oesophagoscope, and this will set a limit to its application. On the other hand, the elastic tube can be introduced after a little experience, and has been used somewhat extensively by a number of surgeons. All short tubes fail when there is perforation into the bronchus, lung, or mediastinum, as fluids cause

irritation. When this stage is reached the long rubber tube—first introduced by Mr. James Berry—must be employed. There are many other questions arising out of the subject which space will not permit me to touch upon. I may refer to my paper published in the *Lancet* for March 30th and April 6th, 1889.—I am, etc.,

London, Feb. 9th.

CHARTERS J. SYMONDS.

#### LONG FREEDOM FROM RECURRENCE AFTER OPERATION FOR CANCER OF THE BREAST.

SIR.—The case published by Mr. Steward, of the woman who had a recurrence thirty-one years after her original operation for cancer of the breast (January 24th, p. 156), has elicited interesting remarks from Sir Anthony Bowly and Drs. Manson and Brown. This case displaces that recorded by Verneuil in *La Semaine Médicale*, 1888, 112, of a woman on whom he operated again for recurrence thirty years after the original operation, which hitherto was the longest recorded interval. Verneuil's patient lived, but for how long is not stated. Bryaut had a twenty-five year interval, with the further curious connexion that the patient had had the cancer for five years before the first operation; the daughter had cancer in her breast but died in six months from the time of her operation. All these three cases, therefore, were more than thirty years from the commencement of the disease.

Mr. Steward and Dr. Manson refer to the cause of the condition being general and not local. I should like to point out, however, that this conclusion is not warranted. Cancer always is local and can only grow where cancer cells exist, and cancer cells start in organs in which there is epithelium, and may be carried to other regions, but they are always local. A general tendency, whatever that means, can never produce cancer in the subcutaneous tissues if cancer cells have not been brought there.

The position of the recurrences a little way from the scar is one of the commonest sites, after the axilla, for recurrences to appear. It is due to the fact that at the operation the knife is kept close to the skin for what is hoped is a sufficient distance, and is then turned deeply through the tissues; in doing this it cuts across the lymphatics and cancer cells escape and remain behind. Many of these cells doubtless die, but some survive and produce recurrences at various times later. In this case there were at least four cells surviving, all of which escaped at the same time, and lay about the same distance from the scar; other cells had already been carried to the internal organ and lay dormant there. How long cells live is unknown; it is only with the greatest difficulty that we can ever find karyokinetic figures in the cells of a constantly changing tissue like the skin, and we must suppose that some cells such as those in the anterior horn of the spinal column, which send their axons to the muscles, must last throughout our lives, as it is almost impossible to imagine that they can ever be replaced. There is no reason to suppose that tumour cells should be less hardy. The answer to the question why they do not grow at once, we must suppose, is that there is a body resistance which prevents them growing, and this resistance varies in different individuals. It is this resistance, or lack of resistance, which determines whether a person has atrophic or acute cancer. This resistance may be very strong for a time, but in almost all cases, if the patient lives long enough, it weakens and disappears and lets the disease work its will, and lucky are those people who, "cured of cancer," die of intercurrent disease in the meantime. In Mr. Steward's case there were apparently internal metastases which proved fatal. The most extraordinary example ever published of this resistance giving way is the case recorded by Crivelli and Tinca; the woman lived with a carcinomatous growth of the breast for forty-seven years, and it was only during the last two years that the resistance broke down and the disease obtained the mastery.

These long intervals between operation and recurrences are very interesting, but what is equally interesting, and even more important for us to know, is the longest period a person has lived after operation for cancer without having a recurrence, and of this no one has any figures.—I am, etc.,

London, W., Feb. 2nd.

DUNCAN C. L. FITZWILLIAMS.

#### A VASCULAR SIGN OF DEATH.

SIR.—In the *Epitome* for January 24th, 1925 (No. 79), reference is made to Dr. M. H. Kahn's claim (*Amer. Journ. Med. Sci.*, December, 1924, p. 890) that segmentation of the venules and arterioles has not hitherto been described as a clinical sign of death.

I was taught this sign at St. Bartholomew's Hospital twenty-five years ago, and on one occasion (when ophthalmic house-surgeon) was examining the retina of a patient with the ophthalmoscope at the moment of death. The column of blood in the veins appeared to stand still, then shake into broken segments. After oscillating to and fro for an immeasurably short period the broken segments came to rest.

Bouchut's description (quoted in Norris and Oliver's *System of Diseases of the Eye*, Lippincott, 1900, vol. iv, p. 917) of "the interruption of the blood current in the retinal veins... recognized by a pneumatosis which at times exists in the meningeal veins" cannot be improved upon.

I think this is the appearance to which Dr. Kahn refers when he says that segmentation of the venules and arterioles is a definite sign of death.

The fact was established by Bouchut in 1876, and several references were made to the phenomenon in the *BRITISH MEDICAL JOURNAL* during 1924 (March 8th, p. 424; March 15th, p. 497).—I am, etc.,

Clifton, Bristol, Jan. 29th.

J. A. NIXON.

#### IODIZED TABLE SALT.

SIR.—The note in your issue of February 7th (p. 274) on this subject calls for a few remarks. There is abundant evidence to prove that vast numbers of people in this and other countries suffer from a deficiency of iodine in their diet. The late Dr. Barwise stated in a newspaper interview that 10 per cent. of the natives of Derbyshire have goitre. If he meant that 70,000 persons in this county have a visible enlargement of the thyroid gland I think there is an element of exaggeration in the statement. Undoubtedly, however, a far larger number suffer in some degree from hypothyroidism (with or without goitre) as the result of partial iodine starvation. Goitre is the result of extreme shortage: minor indications of the defect must be sought elsewhere.

The problem, as you observe, is how to supply the community with the small quantity of iodine they so badly need; and salt as a suitable medium has much to commend it. The amount of iodine appears to be the chief difficulty, and only time and experience can settle the point. I accept Marine's estimate that the body requires 2 grains of iodine a year; but I differ when you proceed to draw from that statement the conclusion that "Any method of giving iodine as a preventive of goitre should therefore aim at providing about 2 grains a year." This assumes that all our iodine intake is to be derived exclusively from iodized salt, which in this country is impossible. Iodine is so widely distributed throughout nature, although present only in minute amounts, that we cannot, not even in goitrous Derbyshire, avoid getting some in our food and drink. The iodine we obtain from iodized salt is intended only to supplement what we get elsewhere; and there is reason to believe that, small though the amount be, if taken regularly from early childhood, it will achieve the end in view.

I have been mainly responsible in advising in an honorary capacity the firms that have marketed iodized salt in this country, and the following points have received consideration in fixing the iodine content:

1. Iodized salt is intended not for treatment, but for prophylaxis only.

2. Once a salt of this kind is put on the market it is impossible to limit its use to goitrous districts. The only prudent course, therefore, is to have the iodine content so low that it can be used without harm, and probably with benefit, by everyone in all parts of the country, leaving supplementary measures, if experience shows them to be necessary, to be employed in those districts where goitre is exceptionally prevalent and severe. In some of the Derbyshire schools an iodized sweet or a chocolate Iodistarin tablet is administered weekly to the children whose parents have consented. Similar auxiliary methods are employed in Switzerland, Austria, and New Zealand; but it is very probable when

iodized salt is universally used from early childhood onwards the need for these supplementary measures will disappear. Time alone can settle the point.

3. Obviously in a new venture of this kind it is better to begin low, and gradually increase the amount if necessary, than to start with a high iodine content, meet with trouble, and bring the whole method into disrepute. It should be remembered that Chatin in Switzerland seventy years ago advocated the use of iodine as a prophylactic for goitre, and the method was very generally used at one time, but it fell into disfavour partly because excessive doses of iodine were employed, but chiefly because the exophthalmic goitre was paraded in a scaremongering fashion, as it will be again. Let us profit by the mistakes of the past.

4. It would be folly, in fixing the iodine content of this salt, not to take advantage of the experience of other countries, Switzerland, Austria, New Zealand, and even "God's own country"—the land where everything is done on a gigantic scale. The Swiss Goitre Commission, after painstaking investigations, fixed the maximum strength about 1 part iodine to 200,000 parts salt, and that is the proportion that has been adopted in this country, except in cases where the salt is intended to be used only at the table, when a strength of 1 in 50,000 has been advised. I am pleased that the Government of New Zealand, in the official instructions it has issued for the preparation of iodized salt, has followed the lead of Switzerland, Austria, and this country rather than America. The strength it has adopted is 1 in 250,000. A special salt with a strength of 1 in 100,000 is permitted, but it must bear a label "Medicated salt," and it must only be used under medical advice.

A much greater proportion of iodine is used in the American iodized salts. Marine says that a concentration of 1 in 500 should be employed in mildly goitrous districts. Surely this is more in the nature of a medicinal preparation than a condiment. It is a hundred times stronger than our table salt, and it contains more than ten thousand times the amount of iodine we would get if we used natural sea-salt for culinary purposes.

Some time ago I asked the Ministry of Health to do what the New Zealand Government has done, and issue instructions or, at least, recommendations, for the guidance of our salt manufacturers. The matter is under consideration. Sir George Newman is, I believe, busy making an exhaustive study of this subject from the material he collected last year from all parts of the country, and his report is eagerly awaited.

My own opinion is that the strongest American iodized salt is perfectly harmless, and that the fear of producing Graves's disease by the use of iodine is quite groundless. In time it may be necessary to increase the iodine content of the salt manufactured in this country; but it is important to note that highly satisfactory results are being obtained in Switzerland and Austria by these weak preparations: and if a small quantity will do what we require, why use more? No one need fear to use freely the British iodized salts. It may be in very bad goitrous regions further iodine assistance may be required; but of no substance can it more truly be said that, however small the amount we receive, every little helps.—I am, etc.,

Chesterfield, Feb. 7th.

J. A. GOODFELLOW.

#### ISOLATION HOSPITALS FOR SCARLET FEVER.

SIR,—A long experience of isolation hospitals, at any rate of those erected in the provinces according to designs approved by the Local Government Board, has convinced me that the designers overlooked one important point—namely, the provision of a covered and wind-protected space for exercise in the open air by convalescents from scarlet fever. In all other respects these modern isolation hospitals are admirable: the sites well chosen; ample air space in the wards; lighting, warming, and ventilation all excellent. But still we find periodical outbreaks of cervical adenitis, otorrhoea, nephritis, etc., which at one time I was inclined to associate almost entirely with temporary crowding of wards, and to deal with accordingly. Later experience has led me to modify these views, and I now think that one of the weak administrative points of these hospitals, if not a direct cause of complications, is the absence of well protected exercising space. In most of these hospitals the wards have been built on hitherto virgin soil, and the immediate surrounding of the wards is newly laid grass with gravel paths on which there is no great amount of regular traffic. In a wet season, such as the summer and autumn of last year, the difficulty of providing open-air exercise for children recovering from scarlet fever became very apparent. It was almost impossible to send the children out without sending them into damp slushy paths and lawns.

The point was emphasized a few years ago when a new phthisis pavilion was added to the hospital buildings in the joint hospital with which I am connected at Hill Top, Bromsgrove. In this pavilion a deep covered verandah is provided along the whole front of each block of cubicles; its advantage is obvious in wet weather. If such a covered space had been available in the scarlet fever and diphtheria blocks I am convinced that some of the complications with which we have been troubled during the last nine months might have been avoided. I am bringing this matter before the committee, but shall be very grateful if others will give their opinion. The additions I advocate would, of course, be rather expensive, but I cannot help thinking that the cost would be justified.—I am, etc.,

H. CAMERON KINN,  
M.O.H. Bromsgrove.

February 8th.

#### HEART STRAIN.

SIR,—Dr. Pullar's comments (January 31st, p. 238) on comparing a leaking aortic valve with the Bramah press are quite reasonable, and one would expect to find that the slightest leak the more serious the effect on the wall of the ventricle. I believe that this would be so were it not for the other very important consideration—namely, the degree of the nourishment of the heart muscle. The slightest leak, as a rule, the better this is, the more able is the heart to compensate well for the extra work thrown on it, and the greater the danger of overlooking early aortic incompetence. With free regurgitation there is very little power of drive through the coronary arteries, and the heart muscle fails badly in consequence of the diminished blood supply to it. The analogy of the effect of the force generated by a leaking aortic valve and that applied in a Bramah press can only be partial, because the wall of the press is absolutely rigid, whilst that of the ventricle is elastic, but it is a convenient reminder of the danger of aortic incompetence.—I am, etc.,

Manchester, Feb. 7th.

E. M. BROCKMANE.

#### WHOLE-TIME MEDICAL OFFICERS.

SIR,—Two letters which appeared in the *BRITISH MEDICAL JOURNAL* of February 7th may, with advantage, be placed side by side and compared. One is from Dr. Crossley, a senior tuberculosis officer, and will be found at page 53 of the SUPPLEMENT; the other, from Dr. Naish, physician, Sheffield Royal Hospital, at page 283 of the JOURNAL.

Dr. Crossley: "We whole-time medical officers... are all, or nearly all, members of the British Medical Association, and are entitled to as much consideration as any other members, and to as much freedom of action in our choice as to what branch of the profession we wish to follow."

Dr. Naish: "If all men were obliged to choose their career immediately upon qualification, there is little doubt, I think, that the resident hospital posts would be given by preference, and rightly so, to those whose choice was private practice as against public services."

Here we have a physician to a great teaching hospital and lecturer in medicine to a medical school approving of discrimination against newly qualified medical men who intended to enter the public services. In the service to which—although no longer on the active list—I still have the honour to belong, young officers, on admission, can be seconded for twelve months for the purpose of holding resident hospital appointments before taking up their work in India. Apparently, these men need not waste time in applying at Sheffield. In the last three generations of my family there have been seven doctors. Of these, two joined the Indian Medical Service, two the R.A.M.C., one the Royal Navy, one is a county tuberculosis officer, and only one elected to "reap the golden harvest"—as Dr. Naish puts it—of private work. As far as I know, we have all held resident hospital appointments.

It would help to clear the air if the British Medical Association would disavow, and as soon as possible, the policy which Dr. Naish proclaims. It should be frankly recognized that there is room for the medical official and the private practitioner. The part of the draft Memorandum of Evidence for the Royal Commission on Insurance that deals with "specialist services" embodies an attack upon the salaried clinical medical officer, and needs entire recasting. The clinic system, and the "team work"

which clinics imply, are now essential parts of the practice of medicine throughout the world. While every officer in charge of a clinic will welcome the association of private practitioners with him in his work, he will naturally resent any attempt to oust him from his appointment and take over the fruits of his labours; and the modifications which the Memorandum suggests are all in the direction of reducing the usefulness and lowering the standard of work at the clinics—a retrograde step which, I believe, the public will not tolerate.—I am, etc.,

P. HEFFERNAN, Major I.M.S. (ret.),  
Tuberculosis Officer, Derbyshire County  
Council.

Buxton, Feb. 7th.

### IMMUNIZATION AGAINST TUBERCULOSIS.

SIR,—There has been much publicity lately on the subject of immunization, more particularly immunization of calves against tuberculosis. In France Dr. Guérin has been using a vaccine made from attenuated cultures. In England Dr. Nathan Raw and Mr. Payne have published results with the use of vaccine R, also from an attenuated culture. The French observers indicate that immunity is not established for more than two years, as a rule. Dr. Raw and Mr. Payne do not yet indicate how long the immunity will last. Dr. Orr of the Rowlett Institute, Aberdeen, in a recent article in the *Transactions* of the Highland Society, indicates that his opinion is that the replenishment of the depletion of the milking cow is the crux of the matter. The Pickett-Thomson Research Laboratory has recently made certain researches in this matter. The writer is one of those engaged in this research. We have attempted immunization at all periods from birth till 1 year old. The matter has been approached from the standpoint of biochemistry, in consequence of the researches of Dr. David Thomson.

We find that all fractions of the tubercle bacillus help to confer immunity, although some are more powerful than others. We find that the length of the immunity depends on the condition of the mother at the time of calving. If the cow is depleted immunity will last for a shorter time, in a calf treated at 6 months old about one year. The earlier the treatment the longer the immunity. Calves from cows with a big milk yield and a big percentage of fat are more apt to have a shorter immunity.

Our results appear similar to those of Dr. Raw and Mr. Payne, but we believe that calves from cows markedly positive to the eye test require more than two doses of vaccine. Our results are at variance with those of Dr. Guérin when he advocates yearly vaccination. We find that if a calf has not a lasting immunity, immunization by the use of vaccine in a sensitive animal may be dangerous. I refer in this instance to animals which remain sensitive from 9 months till 2 years. There is not the same danger in older cattle.

Our researches would almost make us agree with Baumgarten in that it looks as if the virus is in some cases transmitted from the mother. Thus we turned our attention to an attempt to immunize pre-natally. We find that by using the most powerful fraction of the bacillus alone we could render a milking cow which was positive to the eye test negative in about three months. The process was accompanied by great improvement in health, appearance, and milk yield.

The first cow we treated doubled her milk yield in the yearly lactation period. In another cow, aged 10½, markedly depleted and apparently finished, after treatment increased her milk yield from 1,500 gallons to 2,100, and gave birth to twin calves which were all that could be desired. About a dozen cows were so treated. The eye test, it is necessary to note, did not remain negative, but was only positive for a few hours after dropping tuberculin in the eye. The calves of these cows have thriven better, and, we believe, will be easily immunized.

Our complete results indicate that immunization is perfectly feasible. We are at present devising a method of rectifying the negative mineral balance which deep milking cows undergo. Those researches appear similar to the early researches of Sir John McFadyean, who used live human bacilli. We have used a colloidal solution of live

human bacilli. We believe, with Dr. Orr, that the better treatment of depletion is the crux of the matter. From depletion comes tuberculosis. Our researches indicate that where depletion is going on, even when not noticeable in the mother, the calf will show it before the mother breaks down or reacts to the test. If this be true, then early vaccination is imperative if tuberculosis is to be controlled.

In reference to the recent criticism of the detoxication methods of Dr. David Thomson and the defatting method of Professor Dreyer by Dr. L. S. P. Davidson of Edinburgh, it is only fair to recognize that Dr. Davidson himself stressed the fact that he was experimenting with *in vitro* immunity reactions.

I take it that a satisfactory vaccine is one which renders insensitive a very sensitive animal. It enables immunization to take place in an animal sensitive even to the protein and fats of food. In our experiments we attempted immunization of a reacting bull calf at 8 months—mother a reactor; father, history of tubercle probable. We used the fatty fraction of the bacillus, and caused an acute spread of the disease. In the next calf—same mother, same father—we used detoxicated vaccine at birth, later one dose fatty fraction. The second calf passed the test at 8 months and is one of the best heifers in the herd. In our experience, in an animal at 6 months or more, if sensitive and treated by the fatty fraction alone, a spread even to the meninges may occur.

In immunization of cattle heat-killed bacillary emulsions in saline are not good because of the increased sensitiveness. No doubt heat-killed vaccines increase agglutination and complement fixation, but the ultimate aim of immunization is to preserve the integrity of the blood plasma; for the criteria of *plus* agglutinins, etc., are associated with a diminution in the coagulability of the blood. Heat-killed vaccines against infectious pneumonia of calves in the United States of America are an utter failure if given after the disease commences. In this older, more experienced land the farmers save the herds by early bleeding and limiting the extent of the pneumonia.

It would interest those who entertain a belief in lipid that the farmers in Yorkshire are in the habit of making a wound and placing therein a piece of bacon fat when the animal is wasting. The result is usually most successful. But it is only fair to note that the lipid of bacon fat contains a low grade vitamin A, while the lipid fraction of the tubercle bacillus would appear to be vitamin A in great concentration. That the lipid fraction has its place there is no doubt, but not for the young, sensitive consumptive we have to treat. Professor Dreyer is justified in withholding the lipid from his vaccine.

Lastly, in support of the contention that immunity is a matter of biochemistry, I would record that in calves from deeply milking cows where depletion has gone on, milk appears to be, as a feeding stuff, almost poisonous. I learnt that many feeders had known of this for a very long time. We found that in calves desensitized from birth this poisonous character of milk is prevented. Milk in sensitive calves appeared to spread the disease.

That there is a close resemblance chemically between the tubercle bacillus and its products and milk has been recognized in Germany before now, and I think that these researches, given in a tentative way, indicate that there is some close alliance. There is great necessity for research workers in laboratories refraining from expressing results from laboratory animals in terms which have no bearing on disease as seen in practice.—I am, etc.,

J. J. THOMSON,  
Chief Clinical Tuberculosis Officer,  
North Riding of Yorks.

Northallerton, Jan. 14th.

### SHAVING THE VULVA.

SIR,—Will you allow another general practitioner to offer some remarks on the shaving of the vulva before labour?

I offer no opinion on its efficacy in preventing infection; what I am concerned with is its practicability in general practice. It certainly cannot be done by the doctor. It is scarcely reasonable to expect any young woman to submit to such a process at the hands of her medical attendant.

It must be done by the nurses, and how many of them are thoroughly skilled in the work? To remove every hair from the vulva and adjacent parts is a difficult process. Whatever tools are used there will inevitably result a number of more or less minute cuts and abrasions. These are not likely to lessen the risk of infection during childbirth.—I am, etc.,

London, E.12, Feb. 7th.

A. CAMPBELL STARK.

### THE MALIGNANT CELL.

SIR,—The critical analysis of Carrel's latest work given in the BRITISH MEDICAL JOURNAL of February 7th is of such outstanding importance that I ask your permission to comment on the distinction made between sarcoma and granuloma. With the utmost respect and with equal confidence I say that no such difference exists in nature.

A typical human alveolar sarcoma proved to be a granuloma on making a full histological analysis, as is recorded in *Protozoa and Disease*, Part II, Chapter xii; and in the next chapter of the same book a human round-cell sarcoma is shown also to be a granuloma.—I am, etc.,

London, N.W.8, Feb. 8th.

J. JACKSON CLARKE.

### TUBERCULOSIS INCIDENCE AND CLIMATE IN INDIA.

SIR,—I have read the able paper by Sir Leonard Rogers, published last week (p. 256), with the greatest interest and pleasure. The unusually reliable material and wealth of meteorological data, the great area, and the great numbers dealt with, the marked climatic contrasts, and, above all, the high authority of the writer—for there is no greater name in contemporary medicine—make such a confirmation of the utmost consequence to my work. I especially welcome this confirmation at the present moment, when the attention of the profession seems at last really to be turning to the subject.—I am, etc.,

Exeter, Feb. 8th.

W. GORDON.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### Reassembly of Parliament.

The House of Commons reassembled on Tuesday, February 10th. The business of the week included Supplementary Estimates presented by the Ministry of Health. As a grant in aid of payments for medical benefit in England £300,000 was asked, and for medical benefit in Wales £17,000. These additional sums were needed to meet expenditure under the National Health Insurance (Cost of Medical Benefit) Act, 1924. For the additional sickness benefits required "in consequence of heavy sickness in the spring of 1924," £350,000 was asked for England and £3,500 for Wales. The Ministry of Health is not expected to introduce any medical legislation for England and Wales this session, but the Scottish Board of Health will probably reintroduce the Insulin Bill, to authorize the provision of insulin by public authorities in Scotland. Colonel Fremantle (U., St. Albans) has been elected Chairman and Dr. E. Graham Little (Ind., London University) Secretary of the Medical Committee of the House of Commons.

### The Services.

#### DEATHS IN THE SERVICES.

Major Donald Hector Cofin MacArthur, O.B.E., R.A.M.C., was accidentally killed at Meerut on January 23rd. He was born on December 19th, 1880, and educated at Edinburgh, where he graduated M.B. and Ch.B. in 1905 and M.D. in 1913. After filling the post of senior house-surgeon of the Clayton Hospital, Wakefield, he entered the R.A.M.C. as lieutenant on August 1st, 1908, and attained the rank of major after twelve years' service. Brigade Surgeon Francis Collins, R.A.M.C.(ret.), died at Lyme Regis on February 3rd, aged 92. He was born at Knaresborough and educated at Edinburgh, where he took the L.R.C.S. in 1854, and graduated M.D. in 1864. He entered the army as assistant surgeon on September 1st, 1854, became surgeon on March 9th, 1867, and surgeon major in 1873; he retired with a step of honorary rank on January 7th, 1880. In the regimental days he served in the 5th Foot, or Northumberland Fusiliers, and in the 18th Dragoons, and in 1860 was appointed to the Royal Military College, Sandhurst, where he served for several years. He was one of the last survivors of the Indian Mutiny; he took part in the second relief of Lucknow, including the attacks on the Dikusha and La Martinière, and in the occupation and siege of the Alambagh, also in the final relief and capture of Lucknow, receiving the Mutiny medal with two clasps. After his retirement he interested himself in archaeology, contributing many papers to the publications of the Yorkshire Archaeological Society and Surtees Society.

### Medico-Legal.

#### REX v. BATEMAN.

##### PROCEEDINGS IN THE COURT OF CRIMINAL APPEAL.

IN the Court of Criminal Appeal on February 9th the appeal of Dr. Percy Bateman, of New Cross Road, London, against his conviction for manslaughter at the Central Criminal Court on December 12th, was heard before the Lord Chief Justice (Lord Hewart), Mr. Justice Salter, and Mr. Justice Fraser.

Mr. Norman Birkett, K.C., and Mr. Arthur H. Davis appeared for the appellant, and Mr. H. D. Roome for the Director of Public Prosecutions. The court was crowded.

##### The Case for the Appellant.

Mr. Birkett briefly summarized the history of the case on the lines of the opening of his speech on the original application, as reported in our last issue (p. 285). He remarked that, according to Dr. Bateman, the presentation in this labour was the most difficult known to medical science. The head, the feet, and the cord were all presenting together. He complained that Mr. Justice Shearman, in his summing up, had referred to the placenta as "membranous stuff," which might have misled the jury. The placenta was not a thick, fleshy, cake-like substance, a span in breadth, an inch in thickness, and a pound in weight. Continuing, he said that two allegations were made against the appellant, one relating to his conduct of the operation of version and producing the child, and the other to his action in the events which followed thereon. It appeared from the *post-mortem* examination that the injuries which the woman sustained at that time, as described by the medical witnesses for the prosecution, were the destruction of the pelvic floor; the uterus, with the right Fallopian tube and the right ovary, had been removed with the placenta; there was a tear of 2 inches in the uppermost part of the bladder, and there was a crushing of certain intestines against the sacral promontory. There was also a slight tear in the rectum. It was alleged at the trial that some of these injuries might have been caused by natural labour. The expert witnesses stated that the injuries might have been so caused, but that more probably they were the result of the manual traction. Counsel then recapitulated the circumstances which followed the labour, up to the death of the woman seven days later. It was said for the prosecution that the fact that this injury took place at delivery was in itself evidence of such negligence that the jury, on being satisfied that it had taken place, might convict of manslaughter; and that, following these injuries, the omission to do anything with a view to remedying the state of affairs which had resulted was negligence of a kind which rendered a person liable to conviction on the same charge. The answer of the defence was that there was not negligence, and that in so far as the first of these allegations was concerned no single act of negligence was even brought forward by the prosecution, while so far as the second allegation was concerned the conduct which was said by the prosecution to be negligent was, in fact, considered conduct, and, the defence submitted, proper and prudent conduct. Of three cases cited in which the uterus had been removed in a similar manner, one patient died within thirty minutes of such removal, the second died on the way to the hospital, and the third died within forty minutes of admission. The woman in this case lived for seven days.

Mr. Justice Salter desired to know whether negligence was alleged in the manipulation which went on for one hour before the birth of the child.

Mr. Birkett said that this was certainly not admitted by the defence, and it was a matter of some conjecture whether it was persisted in by the prosecution. Sir Bernard Spilsbury had admitted that there was nothing unusual in manipulation for an hour, as in this case, to effect delivery. Counsel then went on to read portions of Mr. Justice Shearman's summing up, and pointed out that there was not one word which made any distinction whatever between what might be termed civil negligence and criminal negligence, although this was a factor of supreme importance in the case. The summing up might be quite unexceptionable in an action for damages against a doctor, but in a direction to a jury on a criminal charge the omission he had pointed out was fundamental. He was conscious of the technical difficulties arising on the distinction between civil and criminal negligence; both things were proved by the same facts, and juries drew inferences from the facts; but unless the clear distinction was made, and the ground of it made, a great injustice could be done. Civil negligence was that negligence in which reparation was sought by the individual; in criminal negligence reparation was sought by the State. In all the discussion with the jury as to the elements which constituted this alleged crime, not one word was said to indicate the distinction between the case in which there was an action for damages and in which the question of degree of skill might enter, and the case in which a person was indicted on

the criminal charge of manslaughter. He appreciated how frail might be the margin between civil and criminal negligence, but in a case like this the sympathies of the jury would obviously be with the husband and with the dead woman, and this made it all the more important to point out that in this case those considerations which might properly be brought to bear in an action for civil damages should not apply. It was a fundamental misdirection to say to a jury that in a criminal charge they could only convict if in their judgement the standard of skill exhibited fell below that which any doctor should possess. In his submission this had no relation to crime at all, although it was entirely admissible in a civil action.

The Lord Chief Justice: There is an implied undertaking of reasonable and competent skill and an obligation to exhibit that skill in fact. You must not say that a doctor who holds himself out to do a doctor's work is negligent because his skill falls short of the highest skill; you can only say that he is negligent in this sense if his skill is not such as it is reasonable to expect of a practitioner.

Mr. Justice Salter: Take a case where there is gross lack of skill, but no lack of care at all. Suppose an unqualified person performs an operation and kills the patient. It is admitted that he did his utmost, used every faculty he had, but could he not be convicted of manslaughter?

Mr. Birkett replied that it would depend on the facts of the case. If his patient knew his lack of qualification and still went to him, the practitioner could not be convicted. Their lordships would remember a case where a man went to a farrier for some operation, and the answer was that if the patient "had not been an ass" he would not have gone to a farrier; and there was no felony. He submitted that in dealing with the crime of negligence to speak of degrees of skill was quite irrelevant.

The Lord Chief Justice: If a person puts himself out as qualified to perform a difficult and delicate operation, he is not, on this argument, to be judged as regards skill by any objective test, but by such skill as in a particular case he happens to have.

Mr. Birkett answered that he appreciated many intellectual difficulties about this matter, but the degree of care and skill which formed the standard whereby the jury must judge—both in civil and in criminal cases, of course—must depend in some degree upon the person with whom they were dealing. If they were dealing with a Harley Street specialist different standards would apply from those which should be taken in the case of an ordinary general practitioner.

The Lord Chief Justice: Do you or do you not assert as a principle of law that under the head of skill the practitioner is to be judged, not by reference to a general standard of skill, but by reference only to such skill as he had shown in a particular case?

Mr. Birkett said that he submitted the latter. He went on to quote from *Bevan On Negligence* to the effect that negligence in one man might be competent care in another, and that where the charge was one of negligent treatment the question of competency or incompetency was irrelevant.

Mr. Justice Fraser pointed out that the passage quoted from *Bevan* went on to declare that the evidence of negligence was not suggested by an arbitrary standard. Given the presumptive competency of the practitioner, the standard of skill required of him, according to this authority, was that of the branch or school to which he belonged.

Mr. Birkett said again that his submission was that this would be perfectly applicable where the issue was one of civil liability, but was not applicable where the issue was one of crime.

Mr. Justice Salter: You agree that in civil matters a man who does his very best may be liable because he is incompetent. Is it contended that in criminal matters a man who has admittedly done his utmost, but is incompetent, is not liable?

Mr. Birkett said that this, without hesitation, was what he would contend. He based his argument for a difference between the two issues on the fact that in the one case—the civil case—the reparation was to the individual, and in the other case—the criminal case—the reparation was to the State, which had suffered injury. There was no injury to the State if a man had done the very best he could.

The Lord Chief Justice: Is there no injury to the State—I am not thinking of this case—if a person, being unskilled, undertakes an operation requiring skill?

Mr. Birkett: Let me take the case of a quack. The quack holds himself out as being able to do certain things and to provide proper treatment, and, knowing he does not possess the skill, he deceives people by so doing. That clearly would be a case where it would be to the interest of the State to say that this was a crime. But where you have a fully qualified medical man doing that which by law he is authorized and required to do, the mere fact that he may fall below the standard of skill in some respect has no reference to a crime, though it may have a reference to civil liability.

The Lord Chief Justice: The lack of the proper quantum of skill or lack of proper diligence in act would not be sufficient to convict. Juries must also be satisfied that by reason of that lack in the one

case or the other, or both, the death of the patient was caused or accelerated.

Mr. Birkett: The real question for the jury would have been this: On these facts is there evidence of gross and culpable negligence which entitles you to say that this man is guilty of manslaughter? That is the question, not the refinements of degrees of skill nor the highly contested medical questions of proper treatment.

Counsel then referred to the case of *Rex v. Van Butchell*, an indictment of manslaughter following upon treatment for disease of the rectum. In the judgement it was stated:

"If a person, bona fide and honestly exercising his best skill to care a patient, performs an operation which causes the patient's death, he is not guilty of manslaughter; and it makes no difference whether such person is a regular surgeon or not, nor whether he has had regular medical education or not."

He also referred to Lord Ellenborough's judgement in the *Williamson* case [set out in the report of his speech in our last issue], and pointed out that nothing was said in Lord Ellenborough's judgement in that case with regard to standard of skill. It was put quite clearly in that judgement that, to convict for manslaughter, either gross ignorance or criminal inattention must be proved. In reply to Mr. Justice Salter, counsel agreed that if a man held himself out to be a skilled man when in fact he was a quack, he could be convicted of manslaughter for pretending to have that skill.

Mr. Justice Salter instanced the parallel case of a motor-driver who, although he might take the utmost care, would not thereby be saved from a charge of manslaughter should he be incapable of proper driving. Mr. Birkett said that the conviction in that case would be on the ground that he purported to have skill as a driver when in fact he had not, but it would not be a question of his standard of skill as compared with other motor-drivers. In the case of a skilled motor-driver the question for the jury would be, not whether in this instance he fell below the general standard of skill of motor-drivers, but whether, with the skill he had, he was negligent on that particular occasion. His degree of skill or the difference between his skill and that of other drivers would be quite irrelevant.

The Lord Chief Justice here referred to the case of *Rex v. Spiller*, in which the judge said:

"Any person, whether a licensed medical practitioner or not, who deals with the life or health of any of His Majesty's subjects, is bound to have competent skill; and is bound to treat his or her patients with care, attention, and assiduity; and if a person dies for want of either, the person is guilty of manslaughter."

Mr. Birkett submitted that if a layman professed to be a medical man and undertook to cure people his action would belong to an entirely different category from that of a medical man who was doing that which he was ordinarily and customarily employed to do. The judgement in this case of *Spiller* went no further than that. It was not there a question as to the exact degree of skill, but as to whether the skill exhibited fell below the general standard of skill of such persons as the defendant in that case.

The Lord Chief Justice remarked that the *Spiller* case dated back to 1832. In 1864 Mr. Justice Wills, in the case of *Reg. v. Markuss*, said that any person who dealt with the health of others was bound to take reasonable care. Gross negligence, said the judge in that case, might be of two kinds. One was that of a physician who, for example, went hunting and left his patients untreated, and the other was that of a physician who was rash in, for example, dealing with dangerous medicines in which he was insufficiently skilled. The judgement continued:

"An unskilled practitioner who ventures to prescribe dangerous medicines, of the use of which he is ignorant, shows culpable rashness for which he will be responsible."

There one had, said the Lord Chief Justice, the twofold division—on the one hand inattention, and on the other hand insufficient skill.

Mr. Birkett, in reply, again cited *Bevan*, to the effect that if a person assumed to act as a physician, however ignorant of medical science, and prescribed with an honest intention of curing the patient, but by ignorance the patient died, the person was not guilty of manslaughter or murder; but if the party prescribing administered the medicine with an obstinate wilful rashness, and not with an expectation of effecting a cure, he was guilty of manslaughter at least, though he might not have intended to effect any harm. To come back to his main contention, counsel said that when the jury were told, "You can only convict this man if you come to the conclusion that he removed the uterus from this woman because his degree of skill fell below that which you would expect of a doctor," it was, in his submission, a misdirection. He then went on to observe that the coroner's deposition which was used in the trial, and upon which Sir Bernard Spilsbury based his evidence, was never proved, and was wrongly admitted, to the injury and detriment of the appellant. Altogether (counsel continued) it appeared that there was no case to go to the jury so far as the operation itself—what he called the first part of the

charge—was concerned. The testimony of the midwife—who had had thirty-seven years' experience and had attended on an average 100 confinements a year—when she was asked whether the doctor did everything he ought to do for this woman, was "Yes, I thought so." It was said that he concealed from the relatives the fact that the uterus had been removed, that in a letter he had suggested that the uterus was merely introverted instead of saying it was removed, that in his original deposition before the coroner there was some variation from the facts placed before the criminal court, and that he had put unnecessary violence upon the placenta instead of "peeling" and "coaxing" it away. As for the charge of concealment from the relatives, let the circumstances be considered. This doctor found that the uterus had come away—a terrible calamity—and he told the husband that the woman was going to die, but was it not mere humanity on his part not to distress the family by particulars of what had happened? This humane reticence was now urged as an element of negligence.

The Lord Chief Justice: Not so much evidence of negligence as evidence throwing light on his state of mind with regard to what he had done.

Mr. Birkett said that the issue for the jury was not what he had done, but how he had done it, and the fact that he had concealed from the relatives what he had done could have no relevance. This could be used only to create prejudice. Upon this first head of the case, therefore—relating to what occurred at delivery—there was nothing to go to the jury. That, in his submission, was what the judge should have ruled, and then he might have asked the jury to consider whether the indictment was sustained by the second head—the subsequent action of the doctor. But to leave the issue at large, so that it was not known upon which part of the case the jury came to their conclusion, did entitle the appellant to come to this court to make his submission. In a civil case a defendant was entitled to know the particulars of the alleged negligence; but in the much more serious matter of a criminal charge—when to a medical man a conviction meant the loss of everything—the allegations were left at large.

The Lord Chief Justice: To take away the placenta is an easy matter. From the fact that a considerable amount of force had to be used in the taking away of the placenta it might be held that the doctor ought to have known that what he had got hold of was not the placenta. Was not the jury entitled to say that?

Mr. Birkett: I submit not. I appreciate the difficulties of precise definition.

The Lord Chief Justice: You used the term "coaxing" the placenta. Might not the jury have thought, after hearing the evidence, that there must be a very great difference between coaxing away the placenta and pulling away the womb?

Mr. Justice Salter pointed out that neither Sir Bernard Spilsbury nor Dr. Buchanan, who was the other medical witness for the Crown, was asked to say anything on this point.

Mr. Birkett said that the evidence of Sir B. Spilsbury was entirely in accord with that of the two eminent obstetricians called for the defence—namely, that the edge of the uterus being torn, thin, and irregular, as indeed was the edge of the placenta, to take hold of the one edge in mistake for the other was the most natural thing at that stage, and thus the uterus came away.

The Lord Chief Justice: You say it came away. The evidence is that it was pulled away with considerable force.

Mr. Birkett next dealt with the second portion of the charge—that relating to the subsequent events. The allegation was that because of what the doctor had done, whether through negligence or not, he had destroyed the pelvic floor, and his first duty, therefore, as a medical man was to repair the pelvic floor so as to prevent what the witnesses termed "herniation." The way to do this was by the operation of stitching. If that had been done it was urged that the patient's life might have been saved, and in any event the exploration for the purpose of the operation would have revealed the injury to the bladder and intestine. It was urged that from the evidence as to the woman's condition she was at some time after the birth in a condition to stand the operation, and it was also put forward contended, on the other hand, that the non-removal of the uterus for operation was not a negligent thing at all, but a carefully considered medical procedure. To have moved the patient in the days directly following this event would have meant probably immediate death. There was no moment later when that would have been a safe and proper thing to do. The necessity for drainage was put in cross-examination. Having regard to the removal of the uterus and the position in which the woman was placed, she had in fact the most effective natural drainage. Everything in the previous similar cases on record pointed against operation and in support of the very conduct which the appellant had followed. The point was

made by Sir B. Spilsbury and Dr. Buchanan that, the uterus and ligaments having been torn away, certain blood vessels were torn at the same time, and that unless some stitching was done to deal with these blood vessels the woman was certain to die. The answer was that the bleeding stopped, and the evidence showed that the clotting was the natural and proper thing for stopping the bleeding. To leave her in the position in which she was left so that there might be some chance of healing before removal was not merely the most humane but the most prudent thing to do.

The Lord Chief Justice: The question is, can a professional man be found negligent for doing what two heads of the profession say they would have done in like circumstances?

Mr. Birkett: And it has to be remembered on the other side that Sir Bernard Spilsbury—for whom I have a very great respect—is not a gynaecologist, but a pathologist.

The Lord Chief Justice went on to say that the frequency or the rarity of such a dilemma had to be considered. Apparently the tearing away of the uterus was a very rare thing. Was a man to be expected to know that if that happened all risks must be taken and the patient must go to hospital? If it were an everyday occurrence it would be different.

Mr. Birkett agreed, and said that this was one of the substantial grounds on which he relied in his plea that there had been misdirection on the evidence. The learned judge had told the jury that that fact did not matter. It was vital to the defence to show that in this very rare occurrence the doctor had done everything that a practitioner ought to do. Sir B. Spilsbury, when asked when operation should have taken place, had said that it would depend upon the patient's condition, and that she should have been operated on as soon as she rallied from a state of collapse. For evidence as to the patient's subsequent condition Sir B. Spilsbury had relied upon statements made by the husband and other members of the family, and had entirely ignored the more skilled evidence of the midwife, who testified that there was no change in the patient from the time of delivery on July 23rd to her removal to the hospital on July 28th.

At this point the hearing was adjourned until the following day. When Mr. Birkett apologized for the length of his speech, the Lord Chief Justice begged him to take his time, in view of the very great importance of the case.

*Tuesday, February 10th.*

On the resumption of the hearing Mr. Birkett said that two matters only remained on which he had to trouble their lordships—misdirection by Mr. Justice Shearman on the evidence, and the plea that the verdict was against the weight of evidence. In the notice of appeal there were fourteen separate heads set out on which misdirection was alleged, but in general the only importance to be attached to these was in respect of their cumulative effect. One matter specially complained of was that the jury might have been led to believe, from the way in which the matter was dealt with by the learned judge, that the evidence for the defence given by Dr. Banister as to the number of similar cases of the coming away of the uterus was of no account. With a lay jury, shocked no doubt by the circumstances of this case, there was need for very careful direction if they were not to be led away by their feelings to the disadvantage of the appellant, and they might easily have believed that the pulling away of the uterus was in any circumstances a grossly negligent thing.

The Lord Chief Justice remarked that it might well be, without any question of negligence, that a doctor would pull at the edge of a torn uterus believing it to be the placenta, but the jury might have considered that the degree of force necessary would have informed him, before matters had gone too far, that he was not trying to remove merely the placenta. His lordship asked further whether it was not legitimate for the jury to say that here was a healthy woman, the mother of four children already, and that it was by some mishandling on the part of the doctor in delivering the child that the uterus was pulled away. Mr. Birkett submitted that that was not legitimate. He complained that the summing up might have led the jury to suppose that the pulling away of the uterus in any event was a sufficient ground for finding negligence under the first head—that is, at the delivery—whereas the real question was whether in the pulling away of the uterus there was in fact negligence.

The Lord Chief Justice pointed out that Sir Bernard Spilsbury had said that considerable force would be needed to bring away the uterus. He also noticed that Mr. Birkett had used three different terms to describe what had taken place—"pulled away," "came away," and, an intermediate term, "came away in the doctor's hands." Mr. Birkett said that he supposed this was the bias of the advocate adopting the language most favourable to the appellant which came into his mind at the moment. Asked how he himself would have summed up on this point, he said, with great deference, that he would have submitted to the

jury, after pointing out the distinction between civil and criminal negligence, that they should put from their minds entirely any idea of convicting the prisoner merely because the uterus was pulled away. They should be told that this event might happen in the hands of the most skilful operator. The question for them was whether at any stage there was any blameworthy act or omission on the part of the doctor. Counsel then went on to attack the verdict on the ground that it was against the weight of evidence. Here he quoted at length from the evidence given by Dr. Bright Banister, obstetric physician to Charing Cross Hospital, who was called for the defence. Dr. Banister had said that the chance of the recovery of this patient must have been very slight indeed. Asked if he agreed with Sir B. Spilsbury that probably there was a period in the days immediately following the catastrophe when she might have been removed for operation, he replied, "Change 'probably' into 'possibly' and I agree." Dr. Banister said further that the best person to judge as to the desirability of her removal was the doctor in attendance; also that with such a presentation and without manipulative interference there might have been a rupture of the uterus, and that it was a well known fact that the uterus could rupture in the course of perfectly normal labour. With regard to the midwife's evidence that in removing the placenta the doctor gave it a sharp pull, Dr. Banister considered that this might be enough to separate whatever attachment of the uterus was left. Dr. Banister had also said that it would be quite possible for a medical man in removing the placenta to remove the uterus and not be aware that he had done so; if there was a tear of the uterus its edge might be mistaken for the edge of the placenta. Dr. Banister did not agree that great force would be needed to tear the uterus—not more force than might reasonably have been used.

The Lord Chief Justice pointed out that counsel, in examining Dr. Banister, had quoted the midwife as saying "he pulled it [the placenta] sharply," whereas what she actually said was "he pulled it, rather sharply."

Mr. Birkett went on to say that similar evidence was given by Dr. Hubert Roberts, senior obstetric surgeon, Queen Charlotte's Hospital. This expert evidence was of a nature completely to exonerate the appellant. Having regard to the responsible and honourable duties of the medical profession, whose members were called upon to meet emergencies at all hours of the day or night, when an untoward thing like this happened (a thing which occurred with extreme rarity), to declare that the doctor was guilty of manslaughter, although two other doctors of the highest standing in the profession had said that what he did they would have done, was to place all the members of the profession in a very hazardous situation, and one which would deter men from entering the profession. On any ground he was entitled to succeed, but especially on the ground that the verdict was unreasonable and against the weight of evidence. He added that a very distinguished obstetric physician was present in court and would give evidence if their lordships desired, but in view of the Lord Chief Justice's remarks when the original application was made for the admission of further evidence, he could not press for an examination of this gentleman.

This concluded the speech for the appellant, which had lasted nearly three and a half hours.

#### *The Case for the Crown.*

Mr. H. D. Roome said that the case for the Crown was well expressed in the judgement which had been quoted in *Reg. v. Williamson*, when Lord Ellenborough said, "a person . . . is not indictable for manslaughter unless he is guilty of criminal misconduct arising either from the grossest ignorance or the most criminal inattention." The two divisions of the present case were illustrated in that judgement. It was said by the Crown that to remove the uterus at all might itself be an act of negligence arising from gross ignorance or gross carelessness. Owing to the extreme rarity of such a tragedy it was put before the jury on behalf of the Crown that they might find that the prisoner must have been either grossly ignorant or extraordinarily careless in not discovering before he had pulled away the uterus that it was not the placenta of which he had hold. Owing to the increased resistance of the uterus he ought to have inferred the true state of things, or at least to have paused for reflection. In the opinion of the witnesses for the Crown he must have used a considerable degree of violence.

The Lord Chief Justice here raised the question of what it was which held the uterus in position. Mr. Roome said that he questioned Dr. Hubert Roberts on that point, and he was proceeding to read his answers, when the Lord Chief Justice remarked that this was in cross-examination of a witness for the defence, and asked whether there was no evidence on behalf of the Crown to show what held the uterus in position. Mr. Roome replied that he did not think there was, but in putting his questions to Dr. Roberts he was acting on expert advice, and Sir Bernard Spilsbury was sitting just in front of him.

Mr. Justice Salter asked if there were not passages in the evidence of Sir B. Spilsbury and Dr. Buchanan expressing the opinion that the removal of the uterus in the circumstances of this case was inconsistent with average care and skill. Mr. Roome replied that that was so.

The Lord Chief Justice: As controversy develops, the perspective changes. Was it a cardinal point in the original case for the prosecution that the fact that the uterus was pulled away involved negligence?

Mr. Roome: The case for the prosecution originally was that it was the subsequent conduct of the defendant which laid him open to a charge of manslaughter.

The Lord Chief Justice: The defendant counters that by saying that his subsequent conduct did not accelerate but in fact delayed the death of the woman. Thereupon the prosecution begins to pay a new degree of attention to this original question of the pulling away of the uterus.

Mr. Roome: It was rather upon the suggestion of the learned judge that both aspects were considered, but more stress was laid by the prosecution upon the second aspect.

The Lord Chief Justice: That is to say, you ended as you began.

Mr. Roome: But there was Sir Bernard Spilsbury's evidence that the uterus required a lot of pulling, also the evidence of Dr. Buchanan. [Counsel here read some of this evidence, which described how the uterus was suspended by the broad ligaments.] It was suggested by the Crown that the mere removal of the uterus in these conditions might, if the jury chose so to regard it, be an act of gross negligence as showing ignorance on the part of the doctor of what he was doing, and the prosecution said that the subsequent conduct of the case showed clearly that the doctor himself thought this was so, because he did not inform the relatives what had happened, he impressed upon the midwife not to tell anybody, he took the uterus home, leaving the placenta behind, and he took no steps to inform anyone at the hospital or to call in another doctor.

The Lord Chief Justice: Is that not rather a perilous line of argument? These things might go to supply a makeweight and make the jury say, "Well, it is shown by his conduct afterwards that he thought it was negligence." But would that alter the character of that which had been done? Suppose that what he did was consistent with quite other views and motives. By bringing in these other things you get confusion of mind, supplementing imperfect evidence, and producing a proof!

Mr. Roome: Much more stress was laid upon the second branch of the case. It was urged that this was no error of judgement. The appellant expected the woman to die, and he said that if she had been dead when he called the next morning he would have given a death certificate.

The Lord Chief Justice: Again supposing that had been so, would it have altered the intrinsic nature of what had been done or omitted?

Mr. Roome: It supplied the motive for what the Crown said was his wicked and criminal inattention.

The Lord Chief Justice: But the question still remains: Was there wicked and criminal inattention? If there was not, you need not trouble about motive.

Mr. Roome: But from the evidence the Crown said that there was. The appellant made no attempt to insert a drainage tube; he omitted to take a second opinion; all that he did was to mention to his locumtenent, on his return to the consulting room, what had happened; he made no attempt to remove the woman to hospital.

The Lord Chief Justice: He says that was good for her.

Mr. Roome: The prosecution says that he did it to prevent anybody from finding out what he had done. When he found out that on the following days she was still alive, and according to the relatives a little brighter, if his object had been to treat his patient in the best way he might have brought a surgeon to her bedside to see whether or not she was fit to be operated on.

Mr. Justice Salter: Supposing he had got a second opinion and taken her to hospital, what is the evidence that her life would have lasted longer?

Mr. Roome: It was hypothetical evidence. In the opinion of the medical men called for the prosecution there was just a chance. Sir Bernard Spilsbury said that he considered she rallied sufficiently to permit of an operation being performed.

The Lord Chief Justice: Does that mean a successful operation? Very often the operation is perfectly successful, but the patient dies!

Mr. Roome: The one chance—a very slender one—of saving or prolonging her life was to have an operation, which might or might not have been successful.

The Lord Chief Justice: That statement involves one view of the facts. Another view was presented—namely, that in the circumstances of this case and in the physical posture in which the patient was lying she was getting at least as efficient drainage.

Mr. Roome: That was the evidence of the appellant himself, and of no other witness. What the Crown contended with regard to drainage was borne out by the two medical witnesses called for the defence.

The Lord Chief Justice then asked what, in all this exceedingly interesting and quite ingenious controversy, became of "proof beyond all reasonable doubt."

Mr. Roome said that it was for the jury, after the judge had ruled that there was evidence to go to them, to say whether they considered the case proved beyond all reasonable doubt.

The Lord Chief Justice: It is for them to say; and it may be for others to say whether they have reasonably said.

Mr. Roome: The jury were urged by the prosecution not to convict this man unless they were absolutely driven to it by the weight of evidence. There was no attempt to snatch a verdict.

The Lord Chief Justice: Nobody would suppose for a moment, Mr. Roome, that you would dream of snatching a verdict. No such thing is suggested.

Mr. Roome went on to say that this case was put particularly high by the prosecution. It was put to the jury that unless they thought that the doctor's conduct was so wicked that they were driven to the conclusion that he was guilty of the grossest inattention towards this unhappy woman they must not convict. What impressed the jury was the callous neglect he showed. He did not call in another doctor, he took the uterus home with him, he concealed the facts of the matter from everybody who might be in a position to give help or advice. Moreover, when he was pressed by the husband to send the woman away, he destroyed the very foundation of his reason now alleged for keeping her at home, and it was when she was weaker that he at last yielded to importunity and sent her to hospital.

The Lord Chief Justice: Suppose—a mere hypothesis—that even at the end of the eleventh hour he had still refused to let her go to hospital, would your criticism have been less or more severe?

Mr. Roome: His conduct would have been at least more consistent. The prosecution do not for a moment accept his story that he was consulting the interest of his patient. Having committed a practically unheard-of blunder, he took every step in his power to conceal it, and that was evidenced by the whole of his subsequent conduct.

The Lord Chief Justice: If that is an accurate representation of the case for the prosecution, the foundation of it was that he made a "colossal blunder" in pulling away the uterus, and that the rest of what happened threw light upon the colossal nature of that blunder. That is not the way in which the case was put at all.

Mr. Roome: Perhaps "blunder" was not the proper word. I should have said "disaster." The case for the Crown was that he was so appalled to think of what he had done that he took steps to conceal it. He wrote to the hospital that the patient had been doing fairly well but was now in a bad way. If the patient had been doing fairly well what excuse was there for not sending her to the hospital long before she was sent? It was not until he was driven to send her to the hospital that he did so. The prisoner had a most fair trial. The jury consisted of men only.

The Lord Chief Justice: That remark seems to suggest that the prisoner could not have had a just verdict if there had been women on the jury. But that might have been an advantage to the prisoner.

Mr. Roome: It was the prisoner's counsel who challenged, successfully, every woman juror who was called.

Counsel went on to submit that there was abundant evidence to support the conviction. Dr. Bateman had been guilty of what Lord Ellenborough described as most criminal inattention.

The Lord Chief Justice asked whether what was meant was that he committed a blunder in taking away the uterus in the belief that he was taking away the placenta, and, having committed the blunder, he proceeded, not to seek to remedy the effects of the blunder, but to conceal the fact of it. Mr. Roome agreed, and the Lord Chief Justice went on to ask whether he would not go a step further and say that he had by reason of that concealment accelerated the death of the patient.

Mr. Roome said that that was one of the points on which the learned judge specially directed the jury. No one could say that the woman would not have died had she been removed to the hospital the next day or the day after. It was idle to say that she could not be removed, for an ambulance was available, and a stretcher to carry her down the stairs. There was a chance, at any rate, of something being done to save her life. The prosecution did not accept entirely the evidence of the two distinguished experts for the defence. These gentlemen never saw this woman, alive or dead, but they came forward with theories which in their view were likely to assist the jury in arriving at a conclusion favourable to the accused.

This concluded the speech for the Crown, which occupied half an hour.

#### *Judgement: Conviction Quashed.*

After a consultation, lasting about seven minutes, with his colleagues on the Bench, the Lord Chief Justice announced the judgement of the Court as follows:

This appellant, Percy Bateman, was convicted at the Central Criminal Court of manslaughter, and was sentenced to six months' imprisonment in the second division. He now, by leave of the Court, appeals against that conviction and that sentence. The Court is of opinion that the appeal ought to be allowed and the conviction quashed. In view, however, of the importance of some, at any rate, of the questions which are raised, we propose to consider our judgement and deliver it on a later date. In the meantime the prisoner is discharged.

Dr. Bateman was then discharged and left the court with his friends.

## Obituary.

SIR ANDERSON CRITCHETT, Bt., K.C.V.O.,  
F.R.C.S.Ed.,

Surgeon-Oculist to the King; Consulting Ophthalmic Surgeon to St. Mary's Hospital, London.

By the death, at the age of 80, of Sir George Anderson Critchett, on February 9th after a short illness, a notable figure has passed from the British medical profession. For many years he had been the doyen of ophthalmic surgeons, and he worthily held the high position he had attained. Until within quite recent weeks he was still at work, displaying all that care and interest in his patients that had marked his whole career.

He might be said to have been born to be an ophthalmic surgeon. He was the eldest son of George Critchett, who was one of a distinguished group of men who, commencing life as general surgeons, broke away to specialize in eye work, and by so doing gave an immense impetus to the study of ophthalmology in this country. Many of these men did their work at the well known general hospitals, some at special-eye hospitals. Sir Anderson did his work in the main at St. Mary's Hospital, where he gathered about him a group of students and instilled into their minds a love of the work of his choice.

Not only could he look back on a career of over fifty years as an ophthalmic surgeon himself, but he was a link with the founders of modern ophthalmology. Sir William Bowman, Jonathan Hutehinson, George Lawson, and George Critchett were the great names in the ophthalmic world in the sixties and seventies of last century, and Anderson Critchett was approaching manhood at the time when the discovery of the ophthalmoscope produced a renaissance in the study of diseases of the eye. "La réputation d'un père est un lourd fardeau pour le fils." But great though his father had made the name, Anderson Critchett undoubtedly added to its repute, and it is safe to say that there are few names of British ophthalmic surgeons better known in the world at the present time.

He received his early education at Harrow, and retained to the end the greatest love for and pride in his old school. The cheers with which he was greeted when he went to Harrow on Speech Day in the summer of 1908, after he had been made a baronet, gave him more happiness than almost any other recognition of that honour. At Harrow he won the prize for English literature, and though he did not gain a place in the eleven he laid the foundations of a good cricketing style which served him well when, later on, he went up to Caius College, Cambridge. At Caius he captained the cricket eleven and made many friends. He graduated in 1867, and immediately after began to study medicine at the Middlesex Hospital. He qualified in 1872, and there followed a period when it seemed almost doubtful whether medicine or music should claim him. He possessed a fine baritone voice and a love for the drama and social qualities, which all combined to draw him away from the serious profession of medicine. His affection for his father and his desire to be of assistance to him proved an effective counterbalance to these attractions, and he soon devoted himself seriously to the study of ophthalmology. He speedily began to acquire a wide reputation, and it is of interest to note that his first published paper, on inoculation in ophthalmic practice, was published in a French journal—*Annales d'Oculistique*—in 1877.

In 1881 he was elected, out of a strong field of candidates, ophthalmic surgeon to St. Mary's Hospital, and it was his work there that finally established his reputation and incidentally built up one of the biggest eye clinics at any of the general hospitals in London. Critchett himself would have been the first to recognize how much he was aided in his work at St. Mary's by the late Henry Juler; they loyally worked together when, a few years later, Juler was co-opted as his colleague.

His career from this time onwards is a simple record of increasing honours accorded to him. There was scarcely an important office in ophthalmic circles in which he did not take his share of work with the full appreciation of his colleagues, both of his own and of the younger generation. He was vice-president of the Section of Ophthalmology.

logy at the Annual Meeting of the British Medical Association in 1886 at Brighton, and again in 1895 when the meeting was held in London; he was president of the Section in 1889 at the Leeds meeting. To name but a few of the other offices he held: In 1894 at Edinburgh, and again in 1899 at Utrecht, he was elected honorary president of the International Ophthalmological Congress; from 1899 to 1901 he was president of the Ophthalmological Society of the United Kingdom, and of the Ophthalmic Section of the International Medical Congress at the London meeting in 1913. In that great gathering from many nations he displayed a tact in affairs that made him not only the doyen of British ophthalmologists, but a recognized leader amongst eye men of all countries. Not a little of his success in this regard was due to his powers of expression. It is given to few to have had such a command of words as he had, whether in English or French. He became surgeon-oculist to King Edward VII in 1901 and received the honour of knighthood in that year. In 1905 King Edward created him a Commander of the Victorian Order, and in 1908 he was raised to the rank of baronet. In 1912, when a new Section of Ophthalmology was started in the Royal Society of Medicine, he was the first president. In 1918, on the foundation of the new Council of British Ophthalmologists, he was elected the first president of that body. In 1919, in recognition of services to King George V War Hospital, he was made a Knight of Grace of the Order of St. John of Jerusalem, and in the same year was created K.C.V.O. Last year (1924) he was elected Master of the Oxford Ophthalmological Congress, of which body he had previously been honorary treasurer. Thus, apart from the honours he received from the King, he had held every honour it was possible for his colleagues to confer on him. Such a record by itself shows the esteem in which he was held by those best able to judge of his work—an esteem which could only be earned by the genuineness of character which gave rise to it. Among other offices he held that of ophthalmic surgeon to the Royal Academy of Music and to the Actors' Association.

He was never a prolific writer, and to the regret of many of his pupils much of his teaching, which would have been of great value, is lost for want of record, but he was a great clinician, and unrivalled as an operator. To see Critchett in the heyday of his skill removing a cataract was to see the perfection of operative technique. Never a hurried or purposeless movement was made, and if any untoward complication had to be met, it was faced with the same steady placidity as if it had been foreseen from the first. Few attained to the perfection and gentleness of his manipulative skill. He did his work so easily and gracefully that it appeared to be the simplest of performances. There was no sign of display, no hint of showiness or sleight of hand. Every operation that he performed was a perfect piece of work. There could be no doubt that he thought and studied continually to maintain this perfection of technique. It is therefore to be expected that his writings should in the main have dealt with operative procedures, cataract extractions, and the treatment by operation of conical cornea. But to judge of his views it was better to hear him in a general meeting of one of the ophthalmological societies or an Annual Meeting of the British Medical Association; then, in a perfect flow of

words, he would give his experience in a manner that made so lively an impression as to be unforgettable. While his communications to society meetings were worth hearing, he was at his best when called upon to do the honours of the occasion in congratulating some colleague upon a success gained or an honour won; then Critchett said the words, and just those sentiments, and in just that manner in which every one of his hearers desired them to be said and would like to have been able to say for themselves. In the teaching of students his habits of work, as well as his words, were contagious and lasting in their impression.

As a man integrity was the hall-mark of his character. As a colleague he was perfect; and he counted amongst his colleagues even the most youthful of the followers of his art and craft. There are not a few who recall with pleasure a few simple words from him that were both a reward for an effort made and a stimulus for further work. To be able to do this we may be sure that Critchett was a happy man, of a courteous breed, with a cultivated largeness of heart, that took pleasure both in his own work and in that of others, and could regard the successes of others not only without envy but with hearty satisfaction.

To few men has it been given to have such a happy and such a full life; happy in his work, happy in his friendships, and happy beyond expression in his family life, he reached the end of his long term of years without ever growing old.

We are indebted to an old friend of Sir Anderson Critchett for the following tribute:

Any dweller in the Cavendish Square district during the last thirty, or even forty, years will miss the presence of the familiar figure of Sir Anderson Critchett. Short but dignified, erect and square-shouldered, clothed with the frock-coat and tall hat of pre-war times, and wearing a muffler well on into the days of summer, his was a well known personality as he strolled along, always leisurely, to his nursing home, his hospital, or, in former years, to watch some cricket at Lord's. Sir Anderson Critchett was the acknowledged doyen of ophthalmic surgeons in this country. He was cradled in the purple. His father before him was the well known ophthalmic surgeon,

SIR G. ANDERSON CRITCHETT.

and he therefore had not to endure the hard struggles and lean years which so many consultants and specialists have had to suffer. Elected at a comparatively early age to the staff of St. Mary's Hospital, he was there associated with such men as Broadbent, Chandle, Edmund Owen, Field, and Malcolm Morris, all of whom added lustre to its school.

There are doubtless few who have begun so early in life to practise in Harley Street and who have carried on work so long, so uninterruptedly, and so successfully. During these years he taught and wrote, but it cannot be said that in either of these directions was he as noted as he was for his technical skill and his charming personality. His steadiness of nerve and dexterity of touch permitted of his carrying out cataract operations even in his 80th year. This long-maintained vigour was, possibly, in part, due to his lifelong abstinence from tobacco and wine, though he took the greatest pleasure in supplying the best of both these luxuries to his friends.

His other great claim to remembrance is the affection and regard which he inspired universally with patients and colleagues. His kindness to his junior colleagues was proverbial. He was entirely free from professional envy, hatred, and uncharitableness. His loyalty to those who brought him patients in consultation enabled them to do their best for their clients. This sincerity and uprightness of character gained for him the affection of patients of all classes.

Although so devoted to the practical side of the profession and so esteemed by his colleagues, yet Sir Anderson never

cared to take any prominent place in the academical or administrative life of medicine. Neither did he hanker after any public notoriety. This trait in his character was doubtless due to his intense appreciation of his home and his friends. Of the former this is not the place to write. But it may be recorded that there are few men in recent times who had a larger circle of intimate friends, particularly in the theatrical, artistic, and literary professions. To the writer he once expressed his appreciation of any men who might be called "clubbable," for this adjective, in Dr. Johnson's day, meant a friendly and sociable soul; and not merely a "club-man." His own favourite club, particularly in the golden days of the late Victorian and early Edwardian years, was the Garrick. His intimate theatrical friends were many, and there are few actors or actresses of note who have not enjoyed his hospitality in Harley Street.

Critchett was blessed with what Antoninus Pius, one of the best and wisest of rulers, summed up as the philosophy of life—*Aequanimitas*. He could suffer fools even gladly, and he

never seemed bored. He had a pretty wit, shown, not in the tedious telling of tales which so often passes for humour, but in that bright play of fancy, which is better described by the French as *esprit*. This faculty he used, not for public fireworks, but to cheer his friends and patients. Compared with some of the present-day tendencies towards sensationalism and publicity, Sir Anderson might be regarded as of the old school. His many friends could not wish for higher praise if by the "old school" is meant devotion to family and friends, sincerity in thought and word, generosity and hospitality, cheerfulness and good humour, long years of strenuous work, loyalty to his profession, and entire devotion to his patients. Had he been asked to write his own epitaph I feel sure he would have said: "Write me as one that loves his fellow men," and many to-day can say of him that he was—

"The dearest friend to me, the kindest man,  
The best conditioned and unwearied spirit  
In doing courtesies."

StC. T.

#### EMERITUS PROFESSOR NICHOLAS KULCHITSKY, M.D.

On the morning of January 29th, which was the 69th anniversary of his birth, Professor Kulchitsky was the victim of an accident at University College, as the result of which he died on the night of the 30th. He had acted as a lecturer in histology at University College since 1921.

In 1910, when he had been professor of histology in the University of Kharkoff for thirty years, he retired so as to give younger men a chance of promotion. In spite of the university's appeal for a reconsideration of his resignation he insisted upon his retirement. But he was not idle for long. He soon accepted a position in the Ministry of Irrigation, and then, in 1912, became the representative (curator) of the Ministry of Education in Kasan. In 1914 he was appointed to the same office in St. Petersburg, where he came into personal touch with the late Czar, who in 1915 appointed him a senator, and in 1916 made him Minister of Education, a position he occupied until the revolution.

He was reluctant to refer to his experiences in 1917, when he was seized and imprisoned, but (for some reason which he never quite understood) escaped the fate that befell his brother ministers. He was allowed to return to Kharkoff, where he earned his living by making soap. He used to explain that in the days when he first took to histology it was customary to use soap for embedding tissues, so that the first business of the histologist was to learn how to make soap. Hence in the time of need he had a craft to fall back on and save himself from starvation. He was able to get his family out of Russia in 1918 after walking all the way from Kharkoff to Sebastopol, which took twenty-two days. But he stayed in Russia for another three years in the hope that his services might be useful to his country.

When he arrived in London in 1921 he was penniless. He was taken on to the staff of the Anatomy Department at University College as a lecturer in histology, and, with the help of a grant from the Medical Research Council, he began the study of nerve endings in muscle, which in 1881 had been the subject of the first of his extensive series of contributions to histological literature.

In 1921 Professor Boeke gave a lecture in London on his researches on nerve endings in striated muscles, and brought his specimens to University College, where he gave a private demonstration in the Anatomy Department. His

results differed from those obtained by previous observers. Hence it was suggested to Professor Kulchitsky that he should investigate the whole subject anew. His work has

had momentous results, because John Irvine Hunter, who was working at University College in 1922, got from Kulchitsky's preparations the ideas for the researches described in the *BRITISH MEDICAL JOURNAL* of January 31st. Kulchitsky described two kinds of efferent nerve endings in striated muscle—one connected with non-medullated, the other with medullated nerves. He was unable to discover a single example of both kinds of nerves going to the same muscle fibre.

Kulchitsky's memoir was published in the *Journal of Anatomy* of January, 1924. The night before his fatal accident he completed the manuscript of a memoir on the nerve endings in the lizard's muscles, and instructed his daughter that it was to be dedicated as a tribute to the memory of his young friend John Hunter.

More than a quarter of a century ago Kulchitsky's name became familiar to all neurologists by reason of the widespread adoption of his modification of Weigert's haematoxylin staining method for myelin. But he has a long record of achievements in histology, including textbooks of histology and microscopical technique, both of which passed through five editions between 1902 and 1912.

In addition to the distinction of being a Russian senator and an emeritus professor of Kharkoff University, he was a Commander of the Legion of Honour, a Privy Counsellor of Russia, a corresponding member of the Imperial Academy, and an honorary member of the Anatomical Society of Great Britain and Ireland.

His technical achievements in histology were superb; and during the last three years it was a cheering sight to see the courtly old man, who had weathered such terrible anxieties, peacefully enjoying the triumphs of his own technical skill and experience.

G. E. S.

#### THE LATE SIR JAMES MACKENZIE.

The funeral of Sir James Mackenzie, M.D., F.R.S., took place at Golders Green Crematorium on the morning of Thursday, January 29th. The service in the chapel was conducted by his nephew, the Rev. D. R. M. Keir of Perth. Besides the widow, Miss Mackenzie, Sir William Mackenzie, K.C., and other members of the family, the congregation

NICHOLAS KULCHITSKY, M.D.

Dr. BANTI, professor of morbid anatomy in the University of Florence, who had given his name to a form of splenic anaemia, has recently died.

### Universities and Colleges.

## UNIVERSITY OF LONDON.

## UNIVERSITY COLLEGE.

**THE** introductory medical course for students who have matriculated in the University of London will begin at University College on Monday, March 2nd. Intending students should apply at once, and should attend at the College on Monday, March 2nd, at 11 a.m.

NATIONAL UNIVERSITY OF IRELAND.

On Saturday, February 7th, the following degrees in the Faculty of Medicine were conferred in the hall of University College, Dublin:

[illegible]

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At the meeting of the Board of the President and Fellows, held on 12th October 1906, the following candidates, having duly passed the required examination, were admitted as Licentiates in Medicine and Members of the College: Cyril James Ussher Annrphy, M.B., B.Ch.; B.A.O. Dubl., M.D.; William Thomas Noonan, M.B. Toronto, Ont.

in Saturday, February 7th, Sir  
President of the Royal College of  
Fellowship  
of conferring the honorary  
an address on "Individual links  
between the Royal Colleges of Physicians of London and Dublin "  
(see page 327).

## Medical News.

It will be remembered that on two previous occasions parties of medical men from other countries have visited Great Britain to study British public health services. A third party, now in this country, was received on February 8th by the Society of Medical Officers of Health, addresses of welcome being given by Professor Kenwood and Colonel S. P. James, of the Ministry of Health. On February 9th the party was received by Mr. Neville Chamberlain at the Ministry of Health, when an address was given by Sir George public health administration. Later in divided into three groups, one going to district, another Leeds and the West Willesden and Middlesex. The party will leave this country on March 24th for the closing conference at Geneva. The visits are arranged by the Health Organization of the League of Nations, with the financial assistance of the Rockefeller Foundation. Similar visits have been paid in other years to Italy, Belgium, Austria, Holland, Denmark, Switzerland, and the United States.

DR. J. R. KAYE, the County Medical Officer for the West Riding of Yorkshire, has been elected President of the Association of County Medical Officers of Health for England and Wales.

A CHADWICK public lecture on international hygiene will be delivered by Dr. E. W. Hope at the Medical Society of London, 11, Chandos Street, Cavendish Square, on Monday, February 16th, at 5.15 p.m., with Sir James Crichton-Browne, M.D., F.R.S., in the chair. On Monday, March 9th, at 8 p.m., in the Inner Temple Hall, Lord Newton will give an address on the necessity for legislation with regard to smoke abatement, with Sir William J. Collins, K.C.V.O., M.D., in the chair. In May Professor Brumpt, of the faculty of medicine in the University of Paris, will give two lectures (in English): (1) how to conduct an antimalarial campaign, and (2) the prophylaxis of sleeping sickness. On June 11th, at 5 p.m., in the Chelsea Physic Garden, Sir Daniel Hall, K.C.B., F.R.S., will discourse on the sources of the fruit and vegetable supply of London. Admission to all Chadwick public lectures is free.

DR. ROWLAND L. THOMAS of Whitland has been appointed coroner for West Carmarthenshire.

THE annual county medical dinner organized by the West Riding Local Medical and Panel Committee will be held at the Hotel Metropole, Leeds, on Tuesday, March 31st, at 6.30 for 7 p.m., when the chair will be taken by Sir Berkeley Moynihan, Bt. Tickets 12s. 6d. (exclusive of wine), to be obtained from Dr. W. Eardley, 50, Burlington Crescent, Goole.

A LECTURE on modern atmospheric conditions will be given before the Royal Society of Arts on Wednesday next, February 18th, at 8 p.m., by J. S. Owens, M.D., A.M.Inst.C.E., superintendent, Advisory Committee on Atmospheric Pollution, Air Ministry. Dr. Owens has written on the rate of settlement of solids in water as well as on atmospheric pollution.

THE Fellowship of Medicine announces that on February 20th Sir James Dundas Grant will lecture on some points in the diagnosis and treatment of tuberculosis and cancer of the larynx, at the Royal Society of Medicine, at 5.30 p.m. Beginning on February 16th, a fortnight's course in medicine, surgery, and the special departments will be held at the Prince of Wales's Hospital, Tottenham. In the mornings there will be demonstrations of modern clinical methods; in the afternoons demonstrations of groups of selected cases and clinics in the various hospital departments; and at 4.30 p.m. each day there will be a special clinical lecture. The opening lecture of the course will be given by Mr. James Sherron on appendicitis. On March 2nd a three weeks' course in medicine, surgery, and gynaecology will commence at the Royal Waterloo Hospital, and include heart disease and diseases of the nervous system, the blood, and the breast. A four weeks' afternoon course in ophthalmology will begin on March 9th at the Central London Ophthalmic Hospital; an operative surgery class will be held by arrangement for an additional fee. The Chelsea Hospital for Women is arranging a special three weeks' course from March 16th. At the Hospital for Diseases of the Chest (Brompton) a fortnight's course begins on March 16th. The Royal Northern Hospital, in conjunction with the Royal Ghost Hospital, is arranging an intensive course in medicine, surgery, and the special departments from March 23rd to April 4th. Copies of the syllabuses of these courses may be obtained from the Secretary of the Fellowship at No. 1, Wimpole Street, W.1.

Irish newspapers announce that Dr. T. Hennessy, Irish Medical Secretary of the British Medical Association, has accepted the invitation of the Government of the Free State to become a candidate for election to the Dail for South Dublin City.

ON and after April 1st next grants made to health visitors will be paid by the Minister of Health instead of the Board of Education. The circular letter in which this change is announced states that on and after April 1st, 1923, the appointment of a woman for the first time to be a health visitor will not be approved unless she has obtained a certificate granted by a central examining body approved by the Minister.

At the meeting of the Nottingham Mental Dispensary Committee, held on January 28th, the town clerk reported that the Board of Control had approved the purchase of Aston Hall and park, comprising 88 acres, and about 56½ acres of adjoining land to be used as a home for mental defectives. The institution will, it is hoped, provide accommodation for 400 beds and a resident staff.

At the meeting of the West Kent Medico-Chirurgical Society at the Miller General Hospital, Greenwich, to-day (Friday, February 13th), at 8.45 p.m., Dr. Harold Pritchard will read a paper on some modern aspects of disease.

The nave of Epsom College War Memorial Chapel will be consecrated by the Bishop of Winchester (visitor of the College) on Saturday, February 21st, at 3 o'clock. Contributors to the war memorial fund who wish to be present at the ceremony should apply for a card of admission to the Bursar, Major Walter L. Giffard, the College, Epsom, Surrey.

MESSRS. MANN, EGERTON AND CO., LTD., have made for Daimler Hire Limited a very luxurious ambulance body for a 45-h.p. Daimler chassis. Special attention has been given to ease of loading and the comfort of the patient's bed, and for his removal from his room folding carriers are provided. Two chairs are fixed for attendants. In addition to lockers there is a wash basin with water supply. Attention has been given to the ventilation and lighting of the body. One aim the makers kept in view is that the ambulance when travelling shall resemble an enclosed limousine.

THE twentieth International Congress of Anatomy will be held at Turin from April 6th to 8th under the presidency of Professor G. Romiti. Titles of papers should be sent to Professor G. Levi, Istituto Anatomico, Corso M. d'Azeglio 52, Turin.

At the meeting of the Medico-Legal Society to be held at 11, Chandos Street, W.1, on Tuesday next, February 17th, at 8.30 p.m., Dr. Godfrey Carter will read a paper on the psychology of the criminal, which will be followed by a discussion.

WE hope to publish next week a memoir of Dr. E. E. Klein, F.R.S., the eminent bacteriologist and histologist, whose death at the age of 80 is announced as we are going to press.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated. Authors desiring reprints of their articles published in the British Medical Journal are requested to communicate with the Financial Secretary and Business Manager, 423, Strand, W.C.2, on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—not necessarily for publication.

ALL communications with reference to advertisements as well as orders for copies of the Journal should be addressed to the Financial Secretary and Business Manager, 423, Strand, London, W.C.2. Attention to this request will avoid delay. Communications with reference to editorial business should be addressed to the Editor, British Medical Journal, 423, Strand, W.C.2.

Communications intended for the current issue should be posted so as to arrive by the first post on Monday or at latest be received not later than Tuesday morning.

The telephone number of the British Medical Association and British Medical Journal is Gerrard 2630 (Internal Exchange). The telegraphic addresses are:

EDITOR of the British Medical Journal, Aitoliway Westrand, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London.

MEDICAL SECRETARY, Midiscera Westrand, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### SNOORING.

"WILTSHIRE" writes: Can any reader of the British Medical Journal kindly advise how to prevent snoring in adult life? The patient, a man aged 50, healthy, has no nasal obstruction, is not a mouth-breather, and only recently acquired this habit.

#### HOUSE DUTY.

"T. D. H." writes: I pay £100 a year rent for my house; I am allowed £50 by the Inland Revenue, but I have to pay house duty on the £100. Is that right?

\* \* \* Yes, it is correct, though the reference is presumably to the house duty chargeable for 1923-24 and prior years, as it has been abolished as for 1924-25 and onwards. The point is that whereas house duty—and income tax under Schedule A—is, like local rates, chargeable on the premises as a whole, the amount of rent to be allowed as representing a professional expense is determined by the portion of the premises used for professional purposes.

### LETTERS, NOTES, ETC.

#### THE INACCURATE ANTIS.

DR. W. D. O'KELLY (Department of Pathology and Bacteriology, University College, Dublin) writes: My attention has been drawn to an article in the *Vaccination Inquirer* of February 2nd by the receipt through the post (anonymously from London) of a marked copy of this publication. The article in question refers to a discussion on the value of the Schick test at a recent meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland. I write to say that the account of my remarks given in the article in question is inaccurate and misleading.

#### INFLUENZA.

SURGEON COMMANDER LLEWELLYN LINDOP, R.N., writes to suggest that in influenza the point of infection is the eye, and that the cough-spray, reaching the conjunctival sac, incubates there and infects the nose by way of the lacrimal duct. He thinks, further, that infection of the respiratory tract is by contiguity of tissue, and that the risk of infection would be diminished if persons travelling in trams, buses, and tubes, in reach of infected coughers, could be persuaded to wear well fitting motor goggles. An ordinary pair of horn spectacles would, he says, be better than nothing, but would not cut off lateral splash.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 36, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 63.

## Remarks

ON

## THE POSSIBILITIES OF EXPLORATORY THORACOTOMY.\*

BY

PROFESSOR GEORGE E. GASK, F.R.C.S.,  
DIRECTOR, SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL.

(With Special Plate.)

THE beginnings of thoracic surgery date from the very earliest times of which we have records. It is evident that Hippocrates was familiar with pleural empyema, and his accounts of the means of diagnosis and the various methods of operation by cautery or cutting are classical.<sup>1</sup> Army surgeons throughout the ages have been called upon to treat wounds of the chest inflicted by spear, arrow, or rifle bullet. Celsus, Ambroise Paré, Wiseman, Guthrie, Larrey, and many others have left records of their various efforts. Yet in spite of the ever-recurring need and the obvious desirability of finding a satisfactory treatment for injuries

FIG. 1.—Method of dealing with gunshot wound involving the diaphragm and lung.

and diseases of the chest, thoracic surgery has never progressed far, and in the great advance which characterized general surgery in the past fifty years it has definitely lagged behind.

The purpose of this paper is to attempt an analysis of this strange lack of progress, to discuss what is possible at the present time, and to hint at some developments for the future. With the establishment of aseptic surgery the fear of suppuration and many of the dangers incident to operations which haunted our predecessors were removed, and yet the chest still remained an unexplored field for the surgeon, a fact which at first sight it seems difficult to understand. The explanation may be found in a widespread, though ill founded, belief that on the opening of one pleural cavity under ordinary atmospheric pressure not only one lung, but both lungs, would collapse and the patient die of asphyxia. This assumption was perhaps encouraged by physiologists, who based their opinion upon animal experiments, and though this is true for certain animals, such as guinea-pigs and dogs, in which the mediastinum is poorly developed, it is not true for man, in whom the mediastinum is a moderately stout structure completely separating the two pleural cavities.

In order to get over this assumed difficulty, surgeons invented complicated and costly chambers in which patients could be placed, either under a positive or a negative

atmospheric pressure, so that the interchange of gases in the blood could be maintained with the minimum of respiratory movements. Under these conditions operations were carried out successfully, and one likes to associate this stage in the evolution of thoracic surgery with the names of Sauerbruch and Willy Meyer and Tuffier, to whom great credit is due. These pressure chambers were, however, far too costly to come into common use in hospitals, and in consequence there was little general advance.

Such was, in brief, the position of thoracic surgery at the advent of the great war. The years 1914 and 1915 were dark days for surgery. Little could be done for the sufferers. Frightful . . . . . angrene, and septicæmia complicated . . . . . of the wounds. The words of a distinguished surgeon remain clear in my memory: "Surgery has gone back to the pre-Listerine age"; by which he meant that all the efforts of the surgeons could not avert suppuration, and that the most to be done for the wounds was incision and drainage. It was then that the ghastly method of the guillotine amputation came into vogue, while for wounds of the chest the routine treatment was to put a pad and bandage over the wound, to administer some opium and an expectorant mixture, and to await

FIG. 2.—Gunshot wound of lung: to show method of exposure and extraction of missile.

developments.<sup>2</sup> In 1916 opportunities for surgery at the front were vastly improved, for surgeons with well equipped hospitals were established close behind the fighting line, and the desire to ameliorate the condition of the sufferers provided a stimulus strong enough to overcome some of our long-cherished prejudices.

About the same period in both the French and British armies surgeons began to question this purely expectant treatment of chest wounds and to consider the possibility of opening the pleural cavity, of removing foreign bodies, and of suturing wounded and bleeding lungs. It was, of course, quite impossible to erect pressure chambers anywhere near the front, and, though the fear of making a wide opening into the chest still persisted, it was determined to make an attempt. With fear and trembling the operations were undertaken, when it was quickly found that the chest could be opened widely under a general anaesthetic, that missiles and portions of bone and clothing which had been driven into the pleural cavity could be removed, and that the chest could be closed completely and the wound heal by first intention. The soundness of the practice was soon recognized, and in a short time it was established as a fit and proper treatment for certain types of wounds.<sup>3</sup>

The establishment of this fact is a landmark in the evolution of thoracic surgery the importance of which must be recognized. It marks the abolition of pressure chambers, with the recognition of the feasibility of opening the chest widely under general anaesthesia without undue risk to

\* Given before the Southampton Division of the British Medical Association on January 14th, 1925.

the patient, and the ability of the surgeon to have the thoracic contents under direct view, to arrest bleeding, and to handle and suture a wounded lung. It must not be forgotten in the consideration of the evolution of this branch of surgery that the use of x rays for the purpose of diagnosis and the localization of foreign bodies and of disease has been a most important aid, though full use of the method could not be made until the technical operative details had been elaborated.

After this brief sketch of the evolution of thoracic surgery let us consider what has occurred since the war. Stimulated by their experiences with the treatment of infected haemothorax, the result of organisms which had been carried into the pleural cavity by a missile, some surgeons thought that the ordinary forms of empyema as seen in civilian practice might be treated by a free opening, irrigation, and subsequent closure. Though a certain number of successful results have been reported, the method on the whole cannot be judged a good one. The reason appears to be that in most of the empyema which arise in civilian practice the source of infection lies in the lung, and that even if the pleural cavity were cleansed, reinfection would soon occur; so that for the present the old and well tried method of incision and drainage should be relied on.

For several years after the war there was a demand for treatment from a number of pensioners who had retained missiles in the chest which were giving trouble. The complaints they made were of shortness of breath, pain in the chest, and, in a certain proportion, of haemoptysis and suppuration. The two following cases are illustrative of the types of operation which were performed.

In 1916 an officer (Captain B.), aged 27, received a shell wound of the chest with retention of a piece of shell in the left lung. He returned to duty in 1918 and remained well until September, 1920, when he had a severe haemoptysis, followed by a succession of small haemorrhages and continued expectoration of blood-stained sputum. A radiogram showed a fragment of shell lying in the lower part of the left lung.

An operation was performed in January, 1921, some four and a half years after the wound. The chest was freely opened by an incision along the ninth rib, the lung was exposed, and the piece of shell found lying in an abscess cavity in the lower lobe of the lung. The fragment of shell was removed, the wall of the abscess cavity dissected away, the space closed with layers of catgut sutures, and the chest then closed.

The operation wound healed well, and the patient was discharged four weeks later. The haemoptysis and expectoration disappeared completely, and subsequent letters showed that the patient made a permanent cure.

A soldier (T. C.), aged 31, was wounded in the Dardanelles by a shrapnel ball which entered the chest behind the left shoulder and lodged in the posterior mediastinum, immediately to the left side of the aorta, every pulsation of which was communicated to the ball. The man complained of pain in the chest, and stated that he was unable to work on this account. In this patient the mediastinum was opened by splitting the sternum down the centre. This gave easy access to the mediastinum, and the ball was removed without opening either of the pleural cavities or doing any damage to the thoracic contents. The sternum was sewn together, and recovery was uneventful, the patient being in hospital under three weeks. Reports received lately show that he has remained well.

These operations may be considered to be the direct outcome of the war, and we may turn now to methods of treating various types of disease.

It is not proposed here to enter into a discussion of the treatment of frank empyema, for this subject has been fully dealt with elsewhere. I do, however, want to inquire into what may be done for those patients who have a collection of pus hidden away in some pocket of the pleural cavity or between the lobes of the lung. In some the pus can be located with the needle, but in others this is not so, and

a long and distressing illness is the result. To illustrate my meaning let me tell you about one of our nurses at St. Bartholomew's Hospital.

During the great epidemic of 1918 this lady contracted influenza, which was followed by a pleural effusion. Later she spat up a quantity of pus, and for a short time it appeared as if this was the end of the affair; but the cough and expectoration of pus recurred, associated with fever, and she was totally incapacitated from doing her work. The condition might have been for tuberculosis, but tubercle bacilli could not be found in the sputum, which was crowded with pus cells and streptococci. Repeated, but fruitless, attempts were made to find pus by needling, and at last an operation was suggested.

The chest was opened widely under a general anaesthetic and an abscess found between the lobes of the lung. The abscess cavity had fibrous walls more than a quarter of an inch thick. This fibrous tissue was dissected away, and the cavity closed by approximation with catgut sutures. The operation was followed by immediate cessation of all symptoms, a rapid recovery, and the nurse is now at work in the hospital. (Figs. 4 and 5.)

I submit that in such conditions there is a good field for sound surgery. What is the result of long retention of pus within the chest? A favourable issue may follow if the patient is able to spit up the pus, or if the lung becomes sufficiently collapsed and fibrosed to close the cavity; but at what expense to the patient! At the best it means

a permanent partial disablement. Often the issue is not favourable, and a condition of chronic bronchiectasis supervenes with all its deplorable sequelae, which are too well known to require elaboration. Should it not be accepted that, in the event of the trial and failure to find pus by the ordinary methods of clinical diagnosis, a deliberate and planned exploration of the chest by open operation should be undertaken? In my opinion such an exploration can now be done with safety, and there is no more reason for allowing pus to remain pent up if it happens to be in the chest than if it were in the abdomen. Exploratory abdominal operations have now become of everyday occurrence, and I can see no reason why exploratory thoracotomy should not become equally familiar to general surgeons.

Another type of case which can be benefited by surgery is the chronic discharging sinus which refuses to heal. These are most distressing cases, which, if left alone, tend to get worse and worse and finally die of tuberculosis, amyloid disease, or bronchopneumonia. The old and rather mutilating operation devised by Estlander may very well be replaced by that known as decortication, which Tuffier has done much to popularize. This operation, if deliberately planned and carried out at a reasonably early stage before fibrotic changes have rendered the lung permanently incapable of expansion, may be expected to yield good results. The following history will illustrate my meaning.

A boy (W. J.), aged 8, had pneumonia in the spring of 1923, followed six weeks later by a left-sided empyema. This was treated at first by aspiration, and then by incision and drainage, but the sinus refused to heal. The left side of the chest became flattened, air entry was poor, the fingers showed clubbing, and there was a constant cough with some deliberate operation was performed for the relief of the imprisoned dense fibrous tissue. This was accomplished by the sacrifice of three inches of the seventh and eighth ribs; a layer of thick fibrous tissue was dissected off the lung, which immediately began to expand. Two months later the boy left hospital, healed, with a good functioning lung. The accompanying pictures will show you the condition before operation and nine months later. (Figs. 6, 7, and 8.)

Tumours of the chest do not offer a great field for exploration because they are more often than not malignant, and no further reference need be made to them now.

FIG. 3.—Gunshot wound of chest, involving both pleural and peritoneal cavities: showing method of suture of lacerated diaphragm.

Innocent tumours, though of much rarer incidence, are found from time to time. They may be fibromata or lipomata, and if not removed may give rise to serious, and indeed fatal, results.

Mr. Dunhill has reported the case of a man, aged 37, from whom he removed a fibroma, weighing 1 lb. 3½ oz. and measuring in the greatest diameter 13½ cm. It was situated in the upper part of the mediastinum and bulged into the right side of the chest. The prominent symptoms were increasing and crippling dyspnoea, cyanosis of the head and neck and upper extremities, and oedema of the right arm. The tumour was completely and successfully removed by an operation by the trans-sternal route, and the patient has had no further trouble.<sup>4</sup>

Amongst the rare intrathoracic tumours mention must be made of teratomata. A considerable number of cases have been described, most of which have been in the mediastinum, though others have occupied one or other of the lungs. These have been well described by Sir Rickman Godlee.<sup>5</sup>

The following pictures demonstrate the condition of a patient at St. Bartholomew's Hospital who had an extraordinary mediastinal tumour which involved the pericardium.

A male (A. A.), aged 21, was seized with a sudden severe attack of pain in the chest, accompanied by great shortness of breath. Physical signs and x rays revealed the presence of a large pericardial effusion and a tumour situated in the upper part of the left side of the chest, and apparently attached to, or pressing against, the heart. Temporary ease was afforded by pericardial paracentesis, but as the condition did not improve and dyspnoea was distressing, it was decided to explore the chest by open operation with the idea of removing the tumour. The trans-sternal, or sternum-splitting, operation was chosen as admitting the best exposure of the upper mediastinum. A large thick-walled cyst was discovered containing some 1,200 c.cm. of dark greenish fluid. It was situated in the mediastinum and was adherent to both the pleural and pericardial membranes. The reason for the pericardial effusion was probably due to a leakage from the cyst into the pericardium. The cyst due to a leakage from the cyst with a little more courage the whole of the cyst might have been dissected out. Recovery was uneventful. The histological examination showed the tumour to be a teratoma, containing cartilage and hypoblastic elements. Professor T. R. Elliott, who sent me the patient, has described the case fully at a meeting of the Association of Physicians. (Figs. 9, 10, and 11.)

There still remains the subject of hydatid cysts. This condition, though luckily rare in England, is a most serious complaint and likely to be fatal. The accompanying picture illustrates the condition, and I am indebted for the notes of the case to Dr. C. R. Hoskyn.

The patient was a male, aged 41, who sought relief on account of vomiting and persistent blood spitting. The physical examination and x rays showed the presence of a mass in the right side of the chest. Scolices were found in the sputum, which continued to be blood-stained. An operation was performed and the cyst was removed, but great difficulties were encountered on account of a communication between the cyst and one of the large bronchi. This unfortunate complication probably accounted for a severe bronchitis or bronchopneumonia, to which the patient succumbed three days later.

After this review of what has actually been accomplished, I think it may fairly be considered as proved that certain types of injury and disease of the thoracic viscera may be well and successfully treated by open operation, that the method adopted is a sound one, that it gives encouraging results, and is worthy of general consideration. It has also been demonstrated that the chest can be opened under general anaesthesia, and that the operative technique, though by no means incapable of improvement, is so far advanced as to justify the belief that with increased experience we may hope for still further developments in the near future.

Let us try now to take a more speculative view of the question and consider what are the possibilities of extending the knowledge and experience that have been gained towards the treatment of other diseases of the chest. A question that is constantly being asked is whether something could not be done for tuberculosis of the lung, or a portion of a diseased lung. This question has proved tempting to many surgeons. As long ago as 1881 it was shown by Gluck, Schmidt, Bloch, Biondi, and others that, in animals, portions or the whole of a lung could be removed

without necessarily causing death. On the strength of these experiments a number of operations for the removal of portions of lung affected by tuberculosis were undertaken.<sup>6</sup>

Although one or two favourable results were reported, including one by Macewen, who, in 1897, removed the whole of one lung for massive disintegrating tuberculosis, the method could not be judged a success. The considered judgement of Sir Rickman Godlee, writing in 1898, is worth quoting:

"With regard to these operations it must be said that they do not seem likely ever to have a very wide application; not only because it is very difficult to be sure that the part on which it is proposed to operate is the only one affected, but also because, in the early stage in which alone surgical interference would be justifiable, there is a fair chance of effecting a cure by other less hazardous measures."

These words are as true now as on the day they were written, and the older one grows the more it becomes evident that the problem of tuberculosis is not to be solved by surgical methods. The disease is preventable, and one must look to hygienists and the Ministry of Health to give us healthy conditions, or to pharmacologists to produce a drug which will kill the bacillus. It is tempting to make some reference to the new remedy which is now under trial, but this is neither the time nor place. Mention, however, should be made of subsidiary methods of surgical treatment which may be of help in those cases of established tuberculosis which will not yield to medical means. I refer to the operation of thoracoplasty, which is designed to bring about collapse of a lung when, owing to adhesions, an artificial pneumothorax cannot be obtained.<sup>7</sup> This operation, which has recently received a stimulus from the excellent work of our Scandinavian colleagues, is of undoubted value in certain selected cases. In this connexion it is interesting to remember that the operation was discussed by Macewen as long ago as 1897 at the International Congress of Medicine: a remarkable prognostication.<sup>8</sup>

A recent interesting development comes with the invention of a thoracoscope, by which the interior of the pleural cavity may be examined and through which adhesions may even be divided.<sup>9, 10</sup>

Passing from tuberculosis, I now come to the vexed subject of bronchiectasis, and here I confess to great difficulty in knowing what to say. Should one aim at the removal of one or more affected lobes of a lung? It can undoubtedly be done, and it has been done and patients have survived.<sup>11</sup> There do not appear to be any difficulties in the operation which should make the method impossible of being developed, in suitable cases. The difficulty, as it appears to me, is that at present we do not really understand the pathology of the disease, and the probability is that there are a number of conditions which may produce the same result. I would suggest that this is a suitable subject for research, and that when the accurate details of the pathology of the condition have been established then we shall have a sound basis for effective treatment. If it is allowable to venture on a prognostication, it is that in the greater proportion of instances it will be found that bronchiectasis could be prevented from occurring, and that surgery will take but a small part in its treatment.

This speculative survey of the realm of chest surgery would not be complete without some reference to the surgery of the heart. There are plenty of references in the surgical literature to sporadic operations on the heart—mostly for conditions the result of wounds or foreign bodies lodging in the wall of the ventricle—but little has been done for diseased processes. For many years suggestions have been made that valvular disease of the heart, attended with stenosis of the apertures might be treated by division of the obstructing membrane. It was suggested long ago by Brunton, who was laughed at for his temerity. Now quite recently we find that the operation has actually been done successfully by Cutler of Boston. His first patient is living, and apparently improved, one year after the operation.<sup>12</sup>

I have tried to place before you a few things which have been accomplished and many things which have yet to be

done: that they can be done is sure. May I conclude with these words of Bacon:

"Men, till a matter be done, wonder that it can be done; and as soon as it is done, wonder again that it was no sooner done."

## THE PATHOLOGY AND TREATMENT OF GENU VALGUM.

BY

CHARLES A. MORTON, F.R.C.S.,

PROFESSOR OF SYSTEMATIC SURGERY IN THE UNIVERSITY OF BRISTOL;  
CONSULTING SURGEON TO THE GENERAL HOSPITAL AND TO THE  
CHILDREN'S HOSPITAL, BRISTOL.

(With Special Plate.)

## THE HISTORY OF THE INVESTIGATION.

IN 1897, when we began to take skiagrams, I had one made of the knee-joints in a case of genu valgum, for the purpose of demonstrating the elongated internal condyle, which most of us believed, at that time, invariably produced the deformity. Instead of showing any change in the lower end of the femur, the skiagram showed that the genu valgum was due, to a large extent at any rate, to a deflection outwards of the upper end of each tibia. Certainly the exact shape of the lower end of the femur could not be determined, as the epiphysis was only imperfectly ossified, but there was nothing in the appearance of the skiagram to suggest that an elongation of the internal condyle existed, or any obliquity of the knee-joint, whereas the deformity in the tibia was quite enough to account for the genu valgum. I published<sup>1</sup> an account of the skiagraphic appearances at the time, and then Mr. Muirhead Little and the late Mr. Noble Smith called attention to the fact that, even without the aid of skiagrams, they had described deformities in the leg bones, rather than in the lower end of the femur, as a cause of genu valgum. Indeed, the latter surgeon had stated that he considered these curvatures in the leg bones, and not elongation of the internal condyle, were the usual cause of genu valgum. In 1898 I published<sup>2</sup> a paper, describing these curves in the leg bones, as revealed by skiagrams, and advocated osteotomy of the tibia, rather than of the femur, and in 1902 delivered a lecture at the Post-Graduate College and Polyclinic, in which I further described the condition of the bones in genu valgum, and considered more fully its treatment, both operative and non-operative. This lecture was published in the *BRITISH MEDICAL JOURNAL* for 1902 (vol. i, p. 1527). In it I have illustrated the various forms of deformity present in the leg bones which cause genu valgum.

This present paper is based on a study of 51 records of the skiagraphic appearances of genu valgum, which I possess, representing the appearances of about 100 limbs (for the skiagram almost invariably represented both limbs). I have also a very large number of the prints of these skiagram negatives, preserved. These 51 records are all that I possess, with the exception of three which are of no value for the present inquiry. They are: (1) a second skiagram taken two years after the first; (2) a relapse after osteotomy; (3) a case which had been previously operated on by another surgeon.

### FREQUENCY AND RELATIVE PROPORTION OF THE CHANGES IN SHAPE OF THE LEG BONES AND THE LOWER END OF THE FEMUR.

In 36 of the 51 cases the epiphysis at the lower end of the femur was not sufficiently ossified to be certain of its shape from the skiagraphic appearance, but in all these

cases there was sufficient deformity in the leg bones, revealed by the skiagram, to account for the genu valgum; and although it is not possible to say for certain that there is no change in shape in the lower end of the femur, yet in many one can be almost certain the knee-joint has not been made oblique, instead of transverse, by an abnormal descent of the internal condyle. Fig. 1 is a good illustration of this group. In 15 cases ossification of the lower epiphysis of the femur has proceeded far enough to be sure whether the line of the knee-joint is transverse or oblique—that is, whether the internal condyle descends abnormally low or not. In 4 of these cases it is obvious that there is no change in the shape of the condyle, and that the knee-joint remains transverse, and therefore that the genu valgum is wholly due to the curvature, or deflection outwards, of the tibia. Fig. 2 is a good illustration of this group. In 5 cases the descent of the internal condyle was very slight, and the genu valgum was clearly mainly due to the curvature of the leg bones. Figs. 3 and 4 illustrate this group. In Fig. 3 a very slight descent of the internal condyle is seen, but Fig. 4 of the leg bones shows that the genu valgum is more due to a deflection out of the shaft of the tibia from just below the head.

In 6 cases the genu valgum is about equally due to an abnormal descent of the internal condyle with obliquity of the knee-joint, and to curve, or deflection out, of the shaft of the tibia. Fig. 5 is a good illustration of this group. Fig. 6 represents the other limb, in which the genu valgum seems to be more due to deformity in the lower end of the femur than to the curve in the leg bones, but this is because the skiagram is taken with the femur abducted. The shaft of the femur, if prolonged above the skiagram, would not ascend parallel to the inner edge of the skiagram, but obliquely, upwards and inwards. The genu valgum in the skiagram of this limb appears greater than in the other limb, because the limb is abducted, but it will be seen in Fig. 7 that the genu valgum is practically equal in the two limbs. Fig. 7 shows the lower limbs in this case.

FIG. 7.—Represents the lower limbs of the patient from whom skiagrams 5 and 6 were taken.

I have one skiagram in which the genu valgum is wholly due to deflection out of the tibia in one leg, and equally due to this deformity and an abnormal descent of the internal condyle in the other leg. I have never seen a case in which the change in the bone causing the genu valgum was greater in the lower end of the femur than in the tibia.

The proportion of deformity may alter as the case progresses. I have the record of a case in which, at the age of 14, the deformity was almost wholly in the leg bones, whereas, two years later, another skiagram showed the genu valgum was equally due to deformity in the femur and the leg bones. One case does not of course, indicate that, as age advances, the change in the femur becomes more marked in proportion to that in the leg bones, but it is suggestive, and an examination of more skiagrams to decide the point would be interesting.

### THE CHANGES IN THE SHAPE OF THE LEG BONES.

The various forms of deformity of the tibia causing genu valgum were described by me in the lecture already referred to, and are represented in diagram 3 of the published lecture, and need not be reproduced in this paper, but Figs. 8, 9, and 10 give a good idea of the common forms of such deformity. In some cases there is a distinct curve out of the shaft of the tibia from just below the head, in others no definite curve, but a sharper angular deflection out, from about one inch below the head, and in others a gradual deflection out of the shaft

from just below the head. All these various types are represented in the diagram published in my paper in 1902. In the form in which there is a sharp angular deflection out of the shaft, about one inch below the head of the tibia, the angle may be so marked as to cause a definite projection, or spur, on the inner aspect of the shaft of the tibia, in cases of genu valgum, has been attributed to the strain on the attachment of the internal lateral ligament of the knee-joint. In some cases it may be so, and its production in this way is suggested by the appearance in the skiagram, in some cases, of a small surface production of new bone; but in other cases the spine is clearly seen in the skiagram to be simply an angular projection of the shaft at the seat of greatest deformity.

In some cases, of which Fig. 11 is an example, there has been a curious correction of one curve by another. There has perhaps been a curve out in the upper part of the tibia which, if not corrected, would have produced genu valgum; and yet another curve is present, nearly correcting, or even overcorrecting, the upper curve, and producing in the final result a certain amount of genu varum. Or there may be a curve in the lower end of the femur producing genu varum, and this may be corrected by the presence of another curve in the leg bones, which corrects the femoral curve, but if present alone would have produced genu valgum. This condition is illustrated in the left limb in the skiagram, Fig. 12. In the right limb genu varum is present, due to femoral curve. In several cases there has been a combination of curvature of the leg bones outwards, producing a marked degree of genu valgum, and an antero-posterior curve of the leg bones, producing the ordinary bow legs.

The condition of the fibula varies very greatly. In some cases, in which the skiagram shows only the upper half of the bone, it is straight, even though there is a marked deformity of the tibia, causing the genu valgum. Figs. 2, 6, and 13 are good illustrations of this. But it is possible that in these cases the fibula is curved out in its lower part, which is not represented in the skiagram, for other skiagrams which show the whole bone indicate that the fibula, though straight in the upper part, yet may curve out in the lower. In some cases of genu valgum the curve out of the fibula in the upper part, yet of the bone is seen to be as marked as that of the tibia; and in some skiagrams, whereas the tibia is deflected outwards from just below the head, without any distinct curve, yet the fibula presents a very distinct curve out in its upper part; in others, again, both bones are gradually deflected outwards, without distinct curve in either.

THE CHANGES IN THE SHAPE OF THE LOWER END OF THE FEMUR.  
The change in the lower end of the femur, which is partly a cause of the genu valgum in some cases, has been

described as an elongation of the internal condyle of the femur, and this was considered by Mikulicz to be due to an increase in the diaphyseal part of the condyle, rather than the epiphyseal. I do not believe there is any change in the shape of the internal condyle itself, but I consider that the internal condyle is pushed downwards, and the obliquity of the knee-joint thus produced, by a change in the shape of the whole condylar part of the lower end of the femur. In a study of skiagrams of these cases, the condylar part is seen to be tilted outwards at its junction with the shaft, so that the relative level of the condyles is altered, and the internal one descends lower than the external. Figs. 5, 6, 13, and 14 show this change in the lower end of the femur very clearly, and the resulting obliquity of the knee-joint. If a careful study is made of skiagrams in which the abnormal descent of the internal condyle is marked, it will be noticed that the outline of the

outer aspect of the femur, at the junction of the shaft and condyles, is altered. It is more curved in an outward direction than in the normal bone, in which there is a more marked curve at the junction of the shaft and condylar portion of the bone on the inner than the outer side, but in these cases of genu valgum with abnormal descent of the internal condyle to a marked degree there is a markedly greater curve on the outer aspect.

Although in the lecture published in 1902 I called attention to the explanation why the deformity of genu valgum disappears on flexing the knee, it may be well to repeat it here. It has been suggested that it is because the articular surface of the tibia rides off the elongated internal condyle on to its posterior aspect, but it is really due to an external rotation of the limb which the surgeon unconsciously performs in flexing the knee. External rotation of the limb tends to mask the genu valgum, and in really due to an external rotation of the limb which the surgeon unconsciously performs in flexing the knee. External rotation of the limb tends to mask the genu valgum, and in

### DESCRIPTION OF SPECIAL PLATE.

- FIG. 1.—To show curves in leg bones. The epiphysis of the lower end of the femur is not sufficiently ossified to indicate the shape of the lower end of the femur, but it seems almost certain that if the knee-joint is oblique it is oblique in the opposite direction to that which would produce genu valgum; probably it is transverse and there is no deformity of the lower end of the femur.
- FIG. 2.—The knee-joint is transverse and there is no deformity in the lower end of the femur, the genu valgum being due wholly to the deflection outwards of the shaft of the tibia. (The picture is made of two separate skiagrams joined together where the light transverse line is seen. It was not possible to get the lower end of the femur and so much of the tibia on one plate.)
- FIG. 3.—There is a very slight abnormal descent of the internal condyle and obliquity of the joint, but Fig. 4 shows that the genu valgum is more due to a deflection out of the shaft of the tibia combined with a slight fibula curve.
- FIG. 4.—Same case as that shown in Fig. 3.
- FIG. 5.—In this limb the genu valgum is about equally due to the deformity in the lower end of the femur and to the curve in the tibia; but in the other limb (Fig. 6) it seems to be more due to the deformity in the lower end of the femur than to the curve in the tibia, but as explained in the text this is only apparent.
- FIG. 6.—Some case as that shown in Fig. 5.
- FIG. 7.—A common form of curve in the leg bones.
- FIG. 8.—A more angular deformity of the tibiae in the upper part, on the inner side, producing in the left limb a tibial spine.
- FIG. 9.—The curve in the left limb a tibial spine.
- FIG. 10.—The curve in the left limb a tibial spine.
- FIG. 11.—In the right leg there is a curve of the tibia out in the upper part which, if not corrected by a curve in, in the lower, would have produced genu valgum. In the left leg there seems to be a tilting of the lower end of the femur, which would have caused genu varum but for the curve out at middle of tibia. This is again corrected by a curve in the lower part.
- FIG. 12.—In the right leg deformity is present of the lower end of the femur, producing genu varum. In the left leg the same condition, but corrected by curve out of leg bones at middle. This, if present alone, that is, without the condylar deformity—would have produced genu valgum.
- FIG. 13.—The tilting out of the condylar part of the femur, causing abnormal descent of the internal condyle and oblique knee-joint, combined with curvature of the tibia, which also contributes to the causation of the genu valgum. This is the skiagram of the case shown in Fig. 18.
- FIG. 14.—To show the same condition of condylar part of femora as in Fig. 13. In Fig. 14 the lower ends of the femur, the knee-joints, are seen; in Fig. 13 the leg bones are also seen. All these skiagrams are from the same case.

flexing the limb of a genu valgum patient the knee is not also rotated out, the genu valgum is not corrected.

### THE NON-OPERATIVE TREATMENT.

I need not repeat in this paper what I said in 1902 about the futility of attempting to reduce the deformity of genu valgum by the application of splints, in out-patient treatment, as a means of moulding the bones into a better position, though no doubt splints or irons, by supporting the soft bone, may allow Nature a better chance of rectifying the deformity as the bone grows. Since that time I have in one case made an attempt to really mould the deformed bones straight by splint traction. As I pointed out in 1902, it is impossible, in out-patients, to apply splints so as to exercise enough continuous pressure on the bones to mould them. But I admitted a girl, aged 9, into the Children's Hospital, and made traction on the deformed bones, watching very carefully that the traction was really constantly maintained, and that it was not producing any pressure sore. I did not adopt the plan of fixing the limb

against an outside splint and making traction against it, as is usually done, for, as I pointed out in my lecture in 1902, pressure applied in this direction is not as desirable as traction applied so as to draw the displaced lower part of the leg inwards, which, if it acts at all, will restore the original shape of the bones. I therefore fixed the leg, the knee, and the lower part of the thigh, on a combination of a back and outside splint, and made elastic traction on the leg in the neighbourhood of the ankle, towards the inner side, by a rubber accumulator.

It required constant care to see the limb did not in any way shift on the splint, and that no pressure sore was produced (Fig. 15). There was  $3\frac{1}{2}$  inches of genu valgum in the limb when placed on the splint, and I was able to reduce it to 2 inches in six weeks. This was too slow a process to induce me to adopt this line of treatment, for by an operation, practically free from risk, I could with certainty have corrected the whole of it, and need not have kept the child confined to bed for so long a time.

#### THE POSITION FOR OSTEOTOMY.

Since I described the method which I adopted for operation on the leg bones in genu valgum in 1902, I have had considerable further experience of it. If the genu valgum is shown by a skiagram to be due entirely to a deformity of the leg bones, or if the deformity of the leg bones is shown in the skiagram to be sufficient to account for the deformity, the condition of the lower end of the femur not being sufficiently ossified to enable the surgeon to be sure as to abnormal descent of the internal condyle, I operate only on the leg bones, and the result is usually quite satisfactory. Figs. 16 and 17 show such a case before and after operation. It would be quite possible in such cases to correct the genu valgum by an osteotomy at the lower end of the femur (Macewen's osteotomy), but the result would be that the knee-joint, which was transverse (normal) before the operation, would have been rendered oblique, with an abnormal ascent of the internal condyle, which cannot be a satisfactory condition of the joint for locomotion. I admit that a transverse osteotomy of the femur just above the condyles is a simpler operation than removal of a wedge from the

FIG. 16.—Case before cuneiform osteotomy of upper end of tibiae.

FIG. 17.—The same case as that shown in Fig. 16, after operation.

upper end of the tibia, but the latter operation corrects the deformity of the bone producing the genu valgum, whereas an osteotomy of the normal lower end of the femur corrects it by producing a new deformity in the previously normal lower end of the femur. Of course, I am writing only of cases in which the genu valgum is not due to deformity of the lower end of the femur. When it is due to this, clearly an osteotomy there may be indicated.

If a skiagram shows that though there is some abnormal descent of the internal condyle, yet the genu valgum is

due much more to curvature of the leg bones, I think we may ignore the condition of the lower end of the femur, and overcorrect the deformity of the leg bones, to make up for the remaining deformity of the femur, though no doubt the ideal operation in all such cases would be to do a double osteotomy, one correcting the deformity of the lower end of the femur, and the other of the tibia, and possibly a third of the fibula also. In cases in which the genu valgum is extreme, and about equally due

FIG. 15.—Showing application of traction to lower part of leg to overcome the genu valgum.

to abnormal descent of the internal condyle (or, as I should prefer to call it, to a bending out of the condylar part of the femur), I have practised osteotomy both of the femur and the tibia. I treated in this way the patient whose genu valgum is shown in Fig. 18 before operation, and in Fig. 19 after operation; Figs. 13 and 14 show the skiagrams of this case. Fig. 14 was taken to show the condition of the lower ends of the femora and the knee-joints, and Fig. 13 the

leg bones on one side. It was the worst case of genu valgum I have ever seen, and there were 17 inches between the feet when he was standing, but even this measurement does not represent the total amount of genu valgum, as he had to overcome a certain amount of it, by rotation out of the lower limbs, before he could stand at all, and that he might be able to do this he stood and walked with a certain amount of flexion of the hips, as is seen in the photograph. But if the combined deformity in the lower end of the femur and the tibia does not produce an extreme degree of genu valgum, I am generally content to perform a transverse osteotomy of the lower end of the femur, or a cuneiform osteotomy of the upper end of the tibia, according to the relative amount of deformity in each.

A good deal of discussion has taken place as to the age when osteotomy should be performed for rickety deformities, including genu valgum, and some surgeons have advised that it should not be performed in young children because of the tendency to relapse owing to the persistence of the softness of the bone. I think it is well to have a definite guide as to the probability of relapse in all cases before undertaking osteotomy; and it has been my practice for many years to take careful charts of the deformity and careful measurements of the degree of the genu valgum, and then to let the children run about freely for six months, and at the end of this time to compare the limbs with the chart and take a fresh measurement of the

FIG. 18.—The case referred to in the text of 17 inches and more of genu valgum. Fig. 13 shows the skiagram of this case.

FIG. 19.—The case shown in Fig. 18 after combined osteotomy at the lower end of the femur and cuneiform osteotomy of the upper end of the tibia in each limb.

genu valgum. If there has been no increase of the deformity then the surgeon has a good indication that he may perform an osteotomy without fear of relapse. It is naturally considered that if there is any enlargement of the epiphyseal junctions present, indicating an active stage of rickets, it should be a contraindication to osteotomy. But it does not seem to be so, at an rate in some cases in which it has persisted for a considerable time, for I have applied the chart and measurement test to such cases and found the

deformity was not increasing, and then performed osteotomy without, at any rate, early relapse.

#### THE NATURE OF THE OSTEOTOMY.

With regard to the nature of the osteotomy I have performed in cases of genu valgum, all I need say with regard to the operation on the lower end of the femur is that I prefer to divide the bone with an Adams saw from the outer side, rather than by Maccewen's method. I have performed a cuneiform osteotomy of the upper end of the tibia for genu valgum in forty-six limbs, combined in several cases with osteotomy of the fibula, and the correction has usually been quite good (see Figs. 16 and 17, showing photographs of a case before and after this form of osteotomy). In the great majority of these cases there has been no division of the lower end of the femur, but an osteotomy of the femur has also been performed in a few cases because the genu valgum has been due to a deformity of the lower end of the femur as well as in the leg bones. In a few of my earliest cases I made a linear osteotomy of the upper end of the tibia, but I soon realized that removal of a wedge was desirable. A study of the skiagrams will indicate the best position for the removal of the wedge. This is usually quite high up, just below the head of the tibia, but in a few cases, where we have to deal with a curve more uniformly affecting the whole shaft, it has to be removed at a lower level, and in one case of an unusual form of curvature I had to remove two wedges at different levels. In my description of the operation in my former paper<sup>3</sup> I referred to the opinion held by surgeons that a cuneiform osteotomy of the upper end of the tibia was a more dangerous operation than a linear osteotomy of the lower end of the femur, because of the danger of wounding the anterior and posterior tibial vessels and nerves, which lie in such close proximity to the bone where the wedge is removed. But I described how, by a very careful method of removal of the wedge, injury to these structures could be avoided, and in the forty-six cuneiform osteotomies I have now performed no injury of these structures has taken place. If the surgeon, either with an Adams saw or a chisel and mallet, cuts freely right through the thickness of the bone, he will be in great danger of wounding either the anterior tibial vessels in the anterior interosseous space, or the posterior tibial vessels and nerve on the posterior aspect of the tibia. The only safe way is to saw out a wedge from the compact tissue of the superficial aspect of the tibia, and then, as I pointed out in my previous paper, the bone must be further removed in pieces, with great care, so as not to run any risk of carrying the chisel, or the point of the Adams saw, beyond the bone, and wounding any of the soft structures around. In removing this cancellous bone, and the posterior compact layer, it is not possible exactly to maintain the wedge shape of the removal of the superficial compact layer, but the space left is sufficiently wedge-shaped throughout the entire thickness of the bone. In many cases the deep layer of the bone was so cautiously removed that the periosteum on the outer and deep aspect of the wedge space was not divided.

The breadth of the base of the wedge must, of course, correspond to the degree of curvature to be corrected. On a careful examination of the skiagram this may be determined, but the most accurate way is to make a paper chart of the deformed bone, as shown in the skiagram, and then to remove from it a wedge which will just correct the deformity, and note the breadth of the base of this wedge. It is always better to remove too little than too much bone, for it is easy, when once a wedge has been removed, to increase its size by taking a further slice off the bone, for with the ends of the bones separated this can be done by one cut of the saw, the soft parts on the deeper and outer aspects of the bone being protected by a copper spatula. But if too wide a wedge has been removed there will be a great risk of overcorrection of the deformity and the production of a certain amount of genu varum. The test as to whether a sufficient amount of bone has been removed is that when the sides of the wedge space are brought in contact the genu valgum is wholly corrected. Nothing short of this will suffice.

In my paper published in 1902 I advocated the removal

of a wedge which was not transverse, but the apex pointed obliquely upwards. I have since found that a transverse wedge is better, and certainly easier to remove. The base of the wedge should correspond to the inner border of the bone, and a line, which would be at right angles to that surface, if it were straight and not somewhat curved, should pass through the centre of the wedge transversely across the bone. I have generally fixed the anterior edge of the wedge space together with a few catgut sutures, either passed through the periosteum or through holes drilled in the edge of the bone. This is not essential, as if the limb is put up on the splint in the fully corrected position, and carefully maintained in that position, the sides of the wedge space will come together if the right amount of bone has been removed, but it will ensure that the sides of the wedge space are approximated, and is, I think, an advantage.

The important question has to be considered as to whether, in addition to removal of a wedge from the tibia, it is also necessary to divide the fibula. I have already described the skiagraphic appearance of the fibula, and pointed out that it may be straight in the upper part, even if the tibia at that level is much curved; but in these cases it is always possible that there may be a curve out at the lower end, for in the less common cases in which the whole fibula can be seen in the skiagram it may sometimes be noted that although the upper part is straight such a curve exists at the lower end. Both in cases in which there is no curve in the fibula in the upper part, corresponding to the curve in the tibia at this level, and in those in which a marked curve is present in the upper part of the fibula, it may be quite possible to rectify the deformity completely by a cuneiform osteotomy of the tibia alone, and I have done this in many cases. In the case shown in Figs. 16 and 17, before and after cuneiform osteotomy of the upper end of the tibia, the deformity was completely corrected without any division of the fibula. After the wedge has been removed from the upper end of the tibia, and before the fibula has been divided, even when the bones can be placed in a perfectly corrected position, I have sometimes noticed that there has been a tendency for the bones to spring back into the old genu valgum position to some extent, and I have then divided the fibula for the purpose of overcoming this, but I have not thereby succeeded in all cases. The more cuneiform osteotomies of the tibia I have performed for genu valgum, the more have I tended to dispense with division of the fibula, even in cases in which a marked curve was present in that bone.

I think if the fibula has to be divided, the ideal place for division, having regard only to the correction of the deformity, would be at the same level as the tibia, but here it is in such intimate relation to the external popliteal nerve, and a little lower to the nerves into which the external popliteal nerve divides, that I have never attempted division here. In one of my early cases I divided the middle of the fibula, which was the seat of greatest curvature in that particular case, but I found the curvature had brought the fibula so abnormally close to the tibia, and so little room was left in the anterior interosseous space, that the danger of wounding the vessel and nerve there was very great. Since then, whenever I have divided the fibula I have done so where it is fairly superficial—that is, in the lower part, not far above the external malleolus, where there is much less danger of wounding the structures in the anterior interosseous space in cases of marked curvature of the fibula approximating it to the tibia in the middle of the leg. I have in many cases divided it at this level, and even excised a quarter or a third of an inch from it, and I have considered that this has enabled me to correct marked deformity, which the cuneiform osteotomy of the tibia did not allow of. So that I think I may say that though in some marked cases division of the fibula is a distinct aid in correction of the deformity, yet in most cases it is not required.

I have found the use of the special splint which I described, and figured, in my paper in 1902 of very great value in maintaining the limb in the fully corrected position; and, as I pointed out in that paper, it is desirable to support the leg bones under the seat of osteotomy with

a pad, because there is a tendency to sinking backwards of the divided bones at that level.

In several cases in which I have found the curvature in the leg bones producing the genu valgum combined with an antero-posterior curve of the tibia producing the ordinary deformity of bow legs I have had to deal with such a combination of deformity by a double osteotomy—the removal of a wedge from the upper end of the tibia for the correction of the genu valgum, and removal of a wedge from the lower part of the bone for the correction of the antero-posterior curve (in this position of course with the base of the wedge anteriorly).

## Lectures

ON

THE SYMPATHETIC INNERVATION  
OF STRIATED MUSCLE.\*

BY

THE LATE JOHN IRVINE HUNTER, M.D., CH.M.,  
CHALLIS PROFESSOR OF ANATOMY IN THE UNIVERSITY OF SYDNEY.

## LECTURE III.—PART I.

## THE PRACTICAL APPLICATIONS.

THE INCONSISTENT RESULTS OBTAINED BY OTHER  
INVESTIGATORS.

In the second lecture attention was called to the evidence in support of the view that the two kinds of striated muscle fibres perform different functions. Only those innervated by the somatic medullated nerves are actively contractile and under the direct control of the will. The slender fibres innervated by the sympathetic non-medullated nerves are not contractile (although their length is passively altered by the activity of the contractile fibres alongside them): their function is to establish plastic tone, to support and maintain the more active and easily exhausted contractile fibres and relieve them of much of the work that would otherwise induce the rapid onset of fatigue.

When the grey rami of the sympathetic distributed to skeletal muscle are stimulated the muscles supplied show no sign of shortening (Bayliss<sup>1</sup>). But, of course, this is to be expected if the sympathetic innervation is responsible for plastic tone of skeletal muscle. The result of appropriate stimulation would be to fix the muscle fibres governed by the sympathetic system at their existing length. Obviously, therefore, atetoid movements or intermittent spasms of muscle, which depend upon the process of shortening of muscle fibres, are not dependent upon the sympathetic innervation of the muscle groups affected. No appreciable improvement of these conditions follows sympathetic ramisection, and their presence is, in general, a contra-indication to the performance of the operation. However, if marked improvement or loss of these features takes place, any remaining rigidity, which may be dependent upon the existence of plastic tone, may then be examined with a view to subjecting the patient to operation so as to enable further progress in education to proceed.

During recent years several writers have strenuously denied that any function of the sympathetic innervation of muscles had been demonstrated by experiment. It is hardly necessary, in view of the consistent results obtained by Langelaan and ourselves, to discuss in detail the reasons for the negative or inconsistent results obtained by other investigators. In some cases the negative results are due to imperfect denervation; in others to the fact that the observers were looking for an effect upon contractility, which, of course, they did not find. Our observations have been confirmed in the case of the dog by Foix,<sup>2</sup> an investigator who was clearly free from any bias in favour of the results that he obtained, apparently unexpectedly.

Moreover, there is the very positive evidence obtained by Orbeli and his collaborators, which was summarized in

\* Delivered by Professor Elliot Smith at University College, February 2nd, 1925.

the BRITISH MEDICAL JOURNAL (September 20th, 1924, p. 534). Orbeli stated in 1923<sup>3</sup> that the direct influence of the sympathetic nerves on skeletal muscle is fixed beyond doubt; the ability of the autonomic fibres to alter the condition and constitution of muscle becomes transferred from a small organ, the heart, to the whole skeletal muscle, thus fulfilling the prophecy of the "chemical tons" of Pfliiger and the "trophic innervation" of Pavlov. The sympathetic system, which controls all the vital properties of muscles and secures for them the greatest use of their reserve strength, must also affect their tone and metabolism. In 1922 Orbeli's collaborator Ginetinsky found that stimulation of the sympathetic while fatigue was beginning to develop or had developed (as the result of stimulating the motor nerve) gradually restored the function of the fatigued and contracted muscle. The effect begins after a long period of latency, increases gradually, and reaches a maximum soon after the cessation of the stimulation of the sympathetic. Moreover, it lasts a long time.

These results are complementary to and consistent with those obtained in our experiments, and by others, as to the effects of adrenaline on fatigued muscle. The only criticism I would suggest of the work done in the Leningrad Medical Institute is that attention has been concentrated too exclusively on the phenomena of fatigue; and no adequate recognition has been given of the fact that the supporting and fatigue-sparing function of the sympathetically innervated muscle fibres is constantly being performed in every action of any muscle.

I want now to consider two factors that have been responsible for much of the discrepancy in the results obtained by various experimenters.

*Avoidance of the Effects of Asphyxia and of Anaemia of  
the Brain Stem.*

It is clear from the argument of the second lecture that the results of loss of plastic tone would be more difficult to observe if any condition existed that would unduly increase the degree of contractile tone. As Dr. Royle<sup>4</sup> has pointed out, asphyxia of the animal would produce this effect. To avoid this complication he employed intratracheal anaesthesia and then oxygenated the animal freely as soon as decerebration was performed. If asphyxia tended to develop later—for example, when the tube in the trachea was too small—the rigidity of all four limbs in extension would become extremely marked, and differences in the tone of the hind limbs due to the loss of plastic tone on one side would be completely obscured. Removal of the cause of asphyxia would invariably remove the tendency for this display of such an exaggerated degree of contractile tone. In several recent papers Walshe has argued that minimal degrees of oxygen in like manner may lead to hyperexcitability of reflex arcs. Evidence is accumulating that this factor may account for "irritative" symptoms following central nervous lesions, as Royle and I have shown. But the effects of asphyxia and anaemia that are manifested as reflex hyperexcitability are foreign to the condition of tone exhibited in decerebrate rigidity. Like the state of spastic paralysis, this condition is to be regarded as being due to a release of function in the nervous system, following the removal of higher levels of nervous activity. The term "release" is employed in the sense advocated by Hughlings Jackson, and developed in the present century by the work of Head and his collaborators. It appears to me that Sherrington's method of decerebration, which should be done in the goat by section of the mid-brain under direct vision, is preferable, for the purpose of observing the presence or absence of plastic tone, to the method of decerebration by anaemia induced by tying the carotid and basilar arteries, which has been introduced by Pollock and Davis. While a preparation made by the method of these Chicago neurologists is unquestionably useful for observing the reflex activities of such an animal, it gives misleading results so far as tone is concerned. It is impossible to be certain in how great an area of the brain stem the cell stations are rendered hyperexcitable by a degree of anaemia that is insufficient to abolish function altogether.

<sup>1</sup> [As the result of a conversation with Professor Orbeli last November I have made certain verbal modifications of his expressions as translated by Dr. Horsley Gantt in the BRITISH MEDICAL JOURNAL.—G. E. S.]

*The Choice of Laboratory Animal.*

The animal selected for our experiments, in the first instance, was the rabbit. Dr. Royle procured an excellent result in the diminution in tone of the hind limb of a spinal rabbit on the side from which the lumbar sympathetic trunk had been removed. This effect was not reproduced in subsequent experiments; and the failure was attributed to the difficulty in this animal of completely excising the sympathetic trunk on the selected side without injury or removal of the trunk of the opposite side. Therefore the goat was used for all our subsequent mammalian experiments. In the second lecture I have already explained why the goat is peculiarly adapted for this type of experiment. In contrast to the goat a carnivorous animal such as the cat shows a capacity for great and numerous variations in the degree of postural tone. The cat does not take up the extensor posture when placed in the supine position. Variation in the degree of contraction in its four limbs imposes varied attitudes upon it; and no doubt in the well oxygenated decerebrate cat the variations in the degree of rigidity of the limbs are to be accounted for in a like manner. Such variations in the degree and selective activity of contractile tone possibly render the effects of loss of plastic tone less apparent than would otherwise be the case and render an analysis of the exact defect in tone more difficult at the outset. For it must be borne in mind, in this connexion, that in the experiments recorded in the literature, practically all of which were performed on cats, differences were found in the degree of tone upon the two sides following unilateral sympathetomy, which was performed in some cases before, and in others after, decerebration. For instance, Dusser de Barenne observed a diminution in tone in five cases out of nine, after removal of the lumbar sympathetic chain. Ueno found differences in the tone of the fore limb after removal of the ganglion stellatum on one side, but attributed the diminution in tone to sensory inhibition due to the wound on this side; but in Royle's experiments this explanation is not admissible. Consequently the problem presenting itself is not to explain negative results, but the inconsistency of the effects. I believe that the factors to which attention has been called in the foregoing discussion explain the failures encountered. This is especially the case when in the past investigators have been seeking to observe quantitative diminution of tone. I have attempted to show that contractile tone is well displayed after sympathetic denervation, and under certain experimental conditions may be present in an enormously exaggerated degree. It is only when qualitative changes due to the selective removal of plastic tone are looked for that the interpretation of effects in any such instance becomes clear.

The thesis maintained in these lectures (that plastic tone is a property of the sympathetically innervated fibres of skeletal muscle) no longer rests solely upon the evidence provided by experimental decerebrate rigidity. For the same effect as that which follows sympathetic denervation in the decerebrate animal is produced by sympathetic rami-

section in human patients in those conditions of spastic paralysis which exhibit all the essential qualities of decerebrate rigidity.<sup>21</sup> The excessive plastic tone characterizing these conditions is removed by the operation of ramisection. The evidence that may be obtained by studying the character of the knee-jerk is of special interest. For in both decerebrate rigidity and in the types of spastic paralysis to which reference has been made, the execution of the knee-jerks, slow before the operation, became brisk in character. This is due to the rapid rate of relaxation of the extensor muscle after completion of the jerk contraction, which replaces the former tendency of the muscle to remain shortened ("shortening reaction") when contraction ceases.

## THE SURGICAL OPERATIONS.

From the reports that have reached us Dr. Royle and I have been convinced that most of the failures have been due to two main causes: (a) the neglect to determine whether voluntary control and excess of plastic tone were present, and (b) faults in the technique of the operation, more especially the failure to cut the appropriate rami communicantes. The long discussion in this lecture (publication of which has been deferred to next week's JOURNAL) should make clear how to choose cases that are likely to benefit from ramisection.

The basic principle of the operation of sympathetic ramisection is that it removes plastic tone. It is only indicated when plastic tone is in excess and hampers the voluntary activities which have persisted in spite of the central lesion. A study of the nature of the spasticity of the spastic limbs, and an estimate of the anatomical defect of the central mechanism responsible for the condition, must go hand in hand, and only when the physiological indications are discoverable is the operation to be undertaken.

With reference to the operation it is a matter of great importance not to remove the sympathetic ganglia, because the unnecessary removal of their control of visceral function is wholly unwarrantable. Dr. Royle attaches great importance to the adoption of the lumbar route for the

operation of lumbar ramisection, not simply because it is for the patient a less formidable procedure than the abdominal route involves, but especially because it permits a clearer view of the rami and a more certain identification of the right ones to avulse.

In the second lecture I indicated which rami should be cut, and why.

## THE OPERATION OF LUMBAR RAMISECTION.

Royle has given the following account of the surgical technique.

The patient should be made to lie on the side opposite to that of operation and should be inclined slightly toward the surgeon, who faces the patient's back. The space between the ribs and the crest of ilium should be made as wide as possible by placing a sandbag beneath the patient,

FIG. 3.—Drawing to represent the arrangement of the rami communicantes passing to the left lumbar nerves in man. After Dr. T. K. Potts. The black bars represent the places where avulsion is effected in the operation of "lumbar ramisection." The letters will facilitate the interpretation (with the help of Fig. 3). A being a grey ramus, B a mixed ramus, and C the sympathetic cord.

or, better still, by using the adjustable support devised for operations on the kidney.

**Step 1.**—The incision is made from the last rib to the crest of the ilium and thence forward to the anterior superior spine of the ilium. If the quadratus lumborum muscle can be palpated, the downwardly directed part of the incision should follow its lateral margin, but if not, the lateral margin of the sacro-spinalis should serve as a guide. The forwardly directed part of the incision should lie about 1 cm. below the aetnal crest of the ilium. This enables the attachment of the external oblique muscle to be exposed. The flap of skin and fascia outlined by this incision is reflected forward to expose the attachments of the latissimus dorsi to the lumbo-dorsal fascia and of the external oblique muscle to the crest of the ilium.

**Step 2.**—The trigonum lumbale Petiti is next defined and from this point forward the oblique muscles are freed from the crest of the ilium to within 6 or 8 cm. of the antero-superior spine of the ilium. In doing this it is possible in most subjects to divide the external oblique through definite tendinous tissue close to its insertion and to avoid cutting the actual muscle fibres. This gives a decided advantage in closing the wound. The internal oblique and the transversus abdominis muscles are divided through the muscle fibres close to their attachment. The dissection is then carried upward and the lumbo-dorsal fascia is divided at the lateral border of the quadratus lumborum. In doing this it may be necessary to cut through the fibres of the latissimus dorsi.

**Step 3.**—The abdominal wall is now free to be thrown forward and after dividing the fascia transversalis the hand can be passed in front of the quadratus lumborum and the psoas muscles until the medial border of the psoas is palpated. Suitable retractors are then placed in position. Care should be taken not to disturb the fascia covering the quadratus lumborum and the fascia covering the psoas muscle.

In a very fat subject, however, the approach to the sympathetic trunk may be rendered more easy by leaving the fascia transversalis intact except at the medial border of the psoas muscle, where it must be pierced to reach the sympathetic trunk. The ganglionated sympathetic trunk can often definitely be palpated where it lies at the medial border of the psoas muscle before it can be seen. The psoas itself sometimes constitutes a difficulty in the adult subject by obscuring the trunk from view, and a suitable retractor is necessary to flatten the muscle. In children and poorly developed subjects this difficulty is not great.

The ganglionated sympathetic trunk will be found lying on the bodies of the lumbar vertebrae near the medial border of the psoas muscle. The abdominal sympathetic trunk on the left side is easy to define, if the medial border of the psoas is sought. In this situation a thin layer of connective tissue passes from the psoas muscles across the psoas on the opposite side. This is easily slit with a blunt dissector and the sympathetic trunk comes into view. On the right side the trunk lies under the lateral margin of the inferior vena cava and is usually placed anteriorly to

the lumbar vessels. This, however, is by no means constant, for on several occasions Royle has experienced difficulty from the lumbar veins crossing anteriorly to the sympathetic trunk. When this occurs the operation may be simplified by removing one or more of these veins. On the left side this complication has not been met, but in young subjects the lumbar arteries can be mistaken for rami communicantes, which they sometimes resemble in size and direction. In a few instances the lumbar lymphatic vessels and an unusually low formation of the receptaculum clyli has made the definition of the sympathetic trunk more difficult. In one instance the lymphatic vessels lay between the sympathetic trunk and the attachments of the psoas muscle. On lifting the lymphatic vessels the rami appeared from under their posterior surfaces, and patient dissection was required to define each structure.

In defining the sympathetic trunk long blunt dissectors are necessary. Royle's dissectors are 25 cm. long and have rounded ends. A long probe with a flat handle and curved on its end like a strabismus hook is useful for lifting the sympathetic trunk when defining its branches. Long straight, or slightly curved, artery forceps, 20 cm. long, are also essential, and four should be provided. The structures of the abdominal wall and abdominal viscera demand a large, broad, and deep retractor. Royle's retractor for use in operations on the average adult is 8.75 cm. wide and 12.5 cm. deep. It is constructed to act as a light-reflecting surface and has a shelf extending forward from its lower edge so as to depress structures medial to the ganglionated cord. The sympathetic trunk and the rami communicantes should be clearly defined before section. The method of dividing the rami communicantes is usually by avulsion.

Each ramus may be seized by a pair of artery forceps and drawn away from its lateral connexions, though in many instances it is necessary to divide a big ramus with a long pair of blunt-pointed scissors. In young subjects the rami may be easily and effectively broken with the blunt dissector. When ramisection of the second, third, and fourth lumbar nerves has been effected, the ganglionated cord is then divided at a level corresponding in position to the fourth lumbar nerve. The operation is then completed. The edges of the lumbo-dorsal fascia are first sutured in the region of the trigonum lumbale. The oblique muscles are then sutured to the crest of the ilium and a special point is made of suturing the tendinous portion of the external oblique to its original attachment and to the adjacent fascia lata. When this is done carefully the raw area on the crest of the ilium comes in contact with a raw area of considerable width on the under surface of the external oblique tendon, and this facilitates adhesion. The lumbo-dorsal fascia and the latissimus dorsi muscles are then sutured. The skin is closed without drainage.

The whole operation should be performed with very little loss of blood except from small vessels occasionally encountered in freeing the oblique muscles. There is no bleeding in the depth of the wound if the approach is

FIG. 10.—Dissection to show right lumbar rami communicantes as seen in the operation of lumbar ramisection. The incision runs from the twelfth rib along the border of the erector spinae muscle and is continued for three inches along the crest of the ilium. The tips of the transverse processes are seen in relation to the quadratus lumborum muscle, and the genito-femoral nerve is seen on the anterior aspect of the psoas.

confined to the plane between the peritoneum and the fascia covering the quadratus lumborum and the psoas muscles. Sharp instruments should not be introduced into this wound. The essential dissection can be done with blunt dissectors and long artery forceps.

The ilio-hypogastric and ilio-inguinal nerves are both drawn forward with the abdominal wall and the ureter with the parietal peritoneum. The incision has been designed so far as possible to divide only fibrous structures in approaching the sympathetic trunk. The internal oblique and the transversus abdominis muscles have, usually, to be divided through their muscle fibres at their insertion to the crest of the ilium. The incision also avoids all important nerves and blood vessels, and, if carefully sutured, should leave the abdominal wall as strong as before the operation.

#### THE OPERATION OF CERVICAL RAMISECTION.

The rami communicantes only are divided in the cervical operation. The sympathetic trunk does not come into the field of operation excepting in the approach to the first thoracic nerve. The rami above the first thoracic nerve are post-ganglionic fibres, but the first thoracic nerve itself usually has both a white and a grey ramus. The sympathetic rami usually enter the nerve roots of the brachial plexus after they emerge from the intervertebral foramina, though occasionally rami join the nerve roots within the foramina.

**Step 1.**—The patient lies with the chin turned away from the side of operation and with a small pillow placed beneath the shoulders. The field of operation is reached through an incision extending from the clavicular insertion of the sterno-mastoid backward and slightly upward across the posterior triangle. In young subjects and in those patients in whom the nerve roots all emerge from behind the scalenus anterior this incision suffices, but occasionally it is necessary to make a second small incision upward along the posterior border of the sterno-mastoid to be sure of reaching the connexions to the fifth and sixth nerves.

**Step 2.**—The platysma is divided and the external jugular vein is secured in the line of the original incision. The anterior layer of the cervical fascia is divided and blunt dissection is then carried out to expose the deeper layer of fascia covering the brachial plexus and the scalenus muscles. Between these two layers of fascia the superficial cervical

FIG. 11.—Diagram to illustrate the arrangement of the cervical rami communicantes on the right side. After Dr. T. K. Potts.

artery will be found occasionally. The transversus colli artery appears in a deeper plane crossing the nerve roots, and in Royle's experience most frequently between the seventh and eighth nerve roots. To obtain a clearer view of the plexus this artery should be tied and divided. The omo-hyoid muscle, appearing in this space, can be retracted downward.

**Step 3.**—In the upper part of the plexus it is necessary to look for and define the phrenic nerve as it lies on the anterior aspect of the scalenus muscle. The nerve

roots are then exposed and traced to the intervertebral foramina. The subclavian artery is identified and pulled forward to expose the eighth cervical and the first thoracic nerve. The rami communicantes are not easy to define. Those to the fifth and sixth nerves may come across the anterior surface of the scalenus anterior to join the nerve trunks or they may come through the muscle itself (Fig. 12). In addition there may be two or more branches; and it is necessary in dealing with each of the nerve roots to be sure that all anterior connexions are divided right up to the intervertebral foramina. Grey rami may join

FIG. 12.—Royle's figure of the rami communicantes, as exposed in his operation of cervical ramisection, modified by Dr. John Beattie and Miss Audrey Russell. Note the three slips of the anterior scalene muscle between which the grey rami to the upper three nerves emerge. Position of clavicle indicated by broken lines.

the nerve roots on their antero-inferior aspects, and in many instances must be sought there. This particularly applies to the eighth nerve. Medullated muscular branches will also be found on the anterior aspect of the nerve roots. These may be confused with sympathetic rami, and if there is any doubt should be removed. When the phrenic nerve receives communications from the fifth cervical nerve it will be found necessary to retract it laterally to get a clearer view of the trunk of the fifth nerve. The greatest difficulty will be found in connexion with the eighth cervical and the first thoracic nerves. In approaching this part of the dissection the first rib should be palpated and the first thoracic nerve sought as it crosses the neck of the rib. This nerve trunk can then be traced into the thorax. The cervical sympathetic trunk will be found on a plane posterior to the subclavian artery, and if it can be well defined no difficulty will be experienced in picking up the communicating rami to the eighth nerve. At this point the trunk usually moves to a more medial position as it travels into the neck, but sometimes it will be found lying upon the root of the eighth nerve. The grey ramus of the first thoracic nerve is found on its superior surface medial to the white ramus, which should be avoided if possible. The rami in this operation may usually be easily broken with a small strabismus hook. After ramisection has been completed the wound is closed by drawing together the edges of the platysma and by suturing the skin without drainage.

(To be concluded.)

## BRAIN ABSCESS OF AURAL ORIGIN.

BY

COURTENAY YORKE, M.D.I.P.OOL,

M.B., B.S.LOND., F.R.C.S.ENG.,

HONORARY AURIST AND LARYNGOLOGIST TO THE LIVERPOOL STANLEY HOSPITAL.

ALTHOUGH brain abscess is by no means a rare complication of suppurative otitis media it is sufficiently uncommon to make the report of such cases a matter of interest. The following are brief summaries of six cases that have been under my care during the past year. Three have recovered completely, one died of a recurrence three months after operation, and two died without the abscess being found at operation.

## CASE I.

A man, aged 37. He had had left otitis media for many years with offensive discharge and granulation tissue. He was admitted to the Ministry of Pensions Hospital, Liverpool, on October 28th, 1923, in a drowsy, semiconscious state. When first seen by me on November 2nd he was comatose; temperature 97°, pulse 40; tongue dry and furred; no eye symptoms.

*Operation.*—The skull was opened through the squamous temporal and half an ounce of fetid pus evacuated from the temporo-sphenoidal lobe. During the operation respiration ceased for about half a minute and was not resumed until the abscess had been opened. Uninterrupted recovery followed, and on December 27th he was able to go home for a few days. On January 25th, 1924, a radical mastoid operation was performed. On February 25th he complained of headache and vomited, and a few hours later became comatose with right-sided convulsions and died.

*Post-mortem examination* revealed a large recurrence in the temporo-sphenoidal lobe. The fatal termination was a great surprise to all, since up to the day of his death the temperature and pulse were normal and the man was going about apparently in good health. On retrospect, symptoms that might have aroused suspicion were slight headache, taciturnity, slowness in answering questions, and a certain moodiness and unsociability.

## CASE II.

A boy, aged 12, was admitted to the Liverpool Stanley Hospital on November 7th, 1923, in a very drowsy condition and with sensory aphasia. The tongue was dry and furred. There were no eye changes. Chronic otitis media with slight offensive discharge was found on the left side. The mother was not aware of any ear trouble.

*Operation.*—The skull was opened as in Case i, without disturbing the mastoid, and a large abscess was evacuated in the temporo-sphenoidal lobe. Recovery was delayed by a large cystic hernia cerebri which had to be partly removed. On February 20th, 1924, a radical mastoid operation was performed. On March 9th he was discharged in good health and with no impairment of mental function.

## CASE III.

A girl, aged 17. On April 5th, 1924, I saw this patient in consultation with Dr. C. L. Forde. There had been a recent attack of influenza with acute otitis media on the left side. Whilst apparently convalescent severe frontal and temporal headaches had set in, with vomiting on one occasion. On examination I found the mind clear and alert and the temperature and pulse normal. No discharge and no mastoid tenderness. No eye symptoms were present and no localizing signs. The possibility of brain abscess was considered, but the indications were not thought sufficient to justify operation. On April 10th she became rapidly comatose and on the following day was admitted to the Birkenhead Borough Hospital in extremis.

*Operation.*—As only the most expeditious measure was practicable the temporo-sphenoidal lobe was rapidly explored through a vertical incision above the ear. No pus was found, but the tension being much increased, a decompression operation was performed. Lumbar puncture revealed many lymphocytes, but no micro-organisms. Temporary improvement followed, but symptoms of meningitis ensued and death occurred on April 29th.

*Post-mortem examination* revealed a large abscess of the left lobe of the cerebellum.

## CASE IV.

A girl, aged 13, was admitted to the Victoria Central Hospital, Wallasey, on May 9th, 1924, with temperature 99.2°, pulse 156, and with foul discharge and granulation tissue in the left ear. On May 11th the condition was worse, with temperature 103.6° and pulse 128. Vomiting was occurring and the child had sunk into a drowsy condition.

*Operation.*—A radical mastoid operation was performed, the dura of both middle and posterior fossae being exposed but not opened. Slight improvement followed, but on May 16th the child became very ill, and on May 17th was deeply comatose with Cheyne-Stokes breathing and complete incontinence. At a second operation the cerebellum was first explored, slight nystagmus having been observed. No pus was found, but on subsequently puncturing the temporo-sphenoidal lobe a large abscess was evacuated. Uninterrupted recovery followed and the child is now in excellent health.

## CASE V.

A man, aged 25, had had left suppurative otitis media since Christmas, 1923. He was admitted to the Victoria Central

Hospital, Wallasey, on July 6th, 1921, with a history of severe headaches and vomiting during the previous three weeks. He appeared to be very ill and lay in a heavy apathetic state. The tongue was dry and furred; temperature and pulse normal; there were no eye changes. Slight rigidity of the posterior cervical muscles was present.

*Operation.*—Cholesteatomatous material was found in the mastoid. The temporo-sphenoidal lobe was explored without result. Subsequently a small abscess was evacuated from the cerebellum through an opening internal to the lateral sinus. The patient made an uninterrupted recovery.

## CASE VI.

A man, aged 48, seen in consultation with Dr. Leggate on October 9th, 1921. During the previous week there had been dizziness, headache, and vomiting, inability to write, and very impaired memory, followed by increasing mental dullness. The tongue was very dry and furred, the temperature and pulse normal. He had had right suppurative otitis media for twenty years. There was slight nystagmus and strabismus with a degree of deficient power in conjugate movement of the eyes towards the affected side.

*Operation.*—The cerebellum was explored by numerous and deep punctures, both mesial and posterior to the lateral sinus, but without result. Exploration of the cerebrum was also negative. Cerebro-spinal fluid escaped under pressure, but was free from cells and organisms. Following the operation he continued in a dull apathetic state, but when spoken to answered questions fairly briskly, although for the most part very incorrectly. He died suddenly on October 22nd.

*Post-mortem examination* disclosed an abscess in the anterior angle of the right lobe of the cerebellum adjacent to the pons.

The foregoing cases illustrate the fact that localizing signs are frequently absent in brain abscess, and that, for this reason, it is often difficult to know whether the cerebrum or cerebellum is affected. In left temporo-sphenoidal abscess word deafness is usually present, but, if the disease be well advanced, the general hebetude will make it impossible to test for sensory aphasia. Crossed hemiparesis and homolateral oculo-motor paresis are, in my opinion, rarely present in temporo-sphenoidal abscess.

In cerebellar abscess nystagmus and some form of ocular paresis are the most frequent localizing signs, but even these are often absent (Cases iii and v), as also are asynergia and homolateral paresis. In my experience the most significant symptom of acute brain abscess is severe pain in the head, which is subject to the most terrible exacerbations. This is an early symptom and is invariably present. It continues until a dull apathetic state ensues, which is the precursor of coma.

Regarding operative treatment, it is agreed that the best procedure is to open the mastoid and endeavour to find the track of the disease. On exposing the dura the presence of a brain abscess is usually either immediately obvious by the escape of pus through a hole in the dura or suspected on account of inflammatory changes in the dura. Occasionally, however, the dura may present a normal appearance, and in such cases the investigation must be carried further by incising the dura and exploring the brain. In Cases iv and v localization of the abscess in the cerebrum and cerebellum respectively was only determined after negative exploration of the cerebellum in Case iv and the cerebrum in Case v.

Should the patient's condition be very critical and the signs be those of temporo-sphenoidal abscess, it is a much safer and quicker procedure not to disturb the mastoid but to make a vertical incision above the ear and explore the brain through the squamous temporal. This was done in Cases i, ii, and iii.

A point in treatment that seems to me of great importance is the making of a large opening in the dura and skull. The mere evacuation of the abscess does not of necessity adequately deal with the situation, for there is a large area of encephalitis around, which, unless decompressed, will maintain increase of intracranial pressure and thereby favour extension of brain infection. A sufficient tissue to relieve itself by forming a temporary hernia cerebri. In the case of temporo-sphenoidal abscess, I do not consider it sufficient to remove merely the roof of the tympanum and antrum. Part of the squamous temporal should be removed as well. For similar reasons cerebellar abscesses, unless very small, should be drained behind or through the lateral sinus as well as internal to it. It is important to remember that a cerebellar abscess is much easier to miss than a cerebral abscess, and may, as in Case vi, elude the most thorough search.

## FOLLICULITIS CAPITIS FULMINANS.

BY

S. WATSON SMITH, M.B., CH.B.ED.,  
BOURNEMOUTH.

This case appeared to me to be so unusual as to be worth recording. In twenty years I had not seen such another, nor have I found any reference to the condition in the literature I possess.

In October, 1923, I was called to see a gentleman of 70 who, while gardening, three days previously, had been bitten by an insect on the back of the neck, just within the hair margin. At first itchy, the bite and its immediate surroundings became within a few hours hot, painful, and swollen. When I saw him there was a patch on the nucha the size of a florin, tense, red, and with its surface studded over with papules and with pustules, each having a hair in its centre. The appearance at first glance rather suggested a commencing carbuncle without the induration. Each pustule I probed with pure carbolic acid, and I ordered repeated hot boracic fomentations. Each morning following for the next few days tinct. iodi mit. (B.P.) was painted over and beyond the patch in an attempt to limit spread. This was hopeless, so that within two weeks the disease had extended out of all control and had spread so as to involve practically the whole scalp, except an area the size of the palm of the hand above the left ear, and about the left "temple"; the spread, however, being at once limited by the edge of the hairy scalp. The small initial patch was made up of an agglomeration of papules which speedily became pustular and of lesions which were pustular from the start; a hair pierced each pustule. The pustules were round, small, and at first tense, of a yellow colour, and did not easily rupture.

When the rapid spread commenced fresh pustules appeared in clusters without any previous papular stage and without any basal

acri flavine in normal saline solution was applied, covered with oiled silk. This dressing was replaced every four hours, being each time carefully packed under any portion of undermined skin. For the next three days the patient was profoundly ill, a subsequent fall in temperature and pulse rate appearing to be rather an ominous sign than otherwise. A smear of pus, stained and examined microscopically, showed masses of pyogenic cocci.

By the twenty-ninth day he had begun to sleep better, to ask for more solid food, and the appearance of the scalp was different altogether. The acriflavine had fixed the infection, which, in a day or two more, was in perfect control, the discharge having almost ceased. The soaks were, however, steadily continued, but with a longer interval between dressings.

Six weeks after the operation the whole scalp was practically healed, but, on account of the destruction of many hair bulbs and follicles, there were patches of baldness, and others, islands, where the hair still existed, the damage to these not having been so complete. In the right frontal region there was a network of fine vessels—a telangiectatic patch.

This case, then, was a coccic pustulosis from the start, there being a slight perifolliculitis as well as the folliculitis of great intensity with little surrounding inflammation and practically no induration; at no time was there any crusting. The rapid spread went by continuous auto-inoculation as well as by burrowing, and there was no appreciable lymphatic gland involvement. The effect of the acriflavine was surprising in the way the infection was fixed and controlled. There had been no seborrhoea of the scalp to begin with, nor was there any skin lesion elsewhere—on body or limbs. The partial vacuum method of treatment might have aborted the mischief at the start or an autovaccine have cured more quickly, had the patient allowed their use.

A=Anaesthetic—gas and oxygen.

infiltration to speak of; the scalp was invaded from behind forwards. The pustules remained discrete, though closely set and crowded, and infection appeared to spread by auto-inoculation and direct extension, so that by and by the whole surface oozed pus, which could also be pushed along, from place to place, under the scalp, welling up at the same time through the follicles and showing the hairs at first taking place. The hairs at first remained

in the aspect of burning and pain which extended with the disease, restlessness, furred tongue, loss of appetite, and these, with the situation of the trouble, made sleep almost impossible. The pain, however, became much less severe as the disease approached its worst. During the first week the temperature steadily rose, reaching its highest (102.4°) on the sixth day, the pulse rate being round about 100. There was what might be called a "negative phase" during the second week, and at the fourteenth or fifteenth day general toxic signs became more evident. The skin was yellowish, although no sign of jaundice was indicated in the conjunctiva or sclerotic; the patient perspired freely, complained of headache, aching in the limbs, and exhaustion. With these symptoms, the distress of mind, and want of sleep in such a highly nervous, active-brained man as the patient was, coupled with a soft mitral and aortic first sound, I felt that he was becoming worse, and he was, in fact, extremely ill. Brandy was given, digitalis, and full doses of ucinel, and he was not allowed to sit up in bed. Eusol soaks were substituted for the boracic fomentations, the scalp being gently swabbed with each change of dressing. The patient, being an anti-vivisectionist, had refused to allow any vaccine or method of treatment which had been learned by experiment upon animals. I, of course, respected his feelings, explaining at the same time the greater risk he must take. An intramuscular dose of 0.5 c.cm. colloidal manganese on the fifth day he refused to allow me to repeat, and no autovaccine could be used.

On the twentieth day there was a fall of blood pressure, he was a little cyanosed, and was breathless on the least exertion. The urine contained pus, strings of mucus, and a trace of albumin, but no sugar, and no casts could be found. These were due to a cystitis consequent upon an enlarged prostate, and now aggravated, likely, by the scanty urine, dorsal decubitus, and lowered resistance. However, greater comfort was attained by turning him prone on his face from time to time, especially for a little before each act of micturition, and by the occasional gr.x hexamine, imperial drink, barley water, etc. These kept the cystitis in temporary control.

On the twenty-second day, under gas and oxygen, the whole scalp was cleaved up and any burrowing pus was tapped; a change over to flavine was made. A gauze pack saturated with 1 in 1,000

Kaposi described a disease which he named "dermatitis papillaris capillitii," an inflammation of the scalp commencing at the back of the neck and spreading upwards towards the crown. It was papular at first, each papule being pierced by a hair; there was much surrounding induration, an occasional pustule, the disease, however, being more strictly limited than in my case and being much more slowly progressive. This case differs in many ways from Kaposi's disease, more particularly in the intense nature of the infection and in its rapid and extensive spread, as also in the absence of much surrounding inflammation and induration. "Folliculitis capitis fulminans" appeared to me to be the most suitable label for such an acute pyogenic folliculitis.

I am indebted to Dr. Maynard Varey for having seen the case for me on several occasions and for having confirmed this record.

## VOLVULUS OF THE SMALL INTESTINE.

BY

J. W. GEARY GRANT, F.R.C.S.,

SENIOR ASSISTANT SURGEON, CARDIFF ROYAL INFIRMARY.

THE cause of the condition found in the case here recorded was undoubtedly adhesions of the lower ileum forming a mass, which the enlarging uterus caused to rotate.

A married woman, aged 24, a patient of Dr. Henry Paterson of Cardiff, was transferred from the Maternity Hospital to the Royal Infirmary on November 24th, 1924, with the following history.

The patient, who was seven months pregnant, was seized at 4 p.m. on the previous day with severe epigastric pain, which in a few hours became generalized over the whole abdomen and "doubled her up." This was accompanied by severe and persistent attacks of vomiting. On November 10th she had had a similar attack of pain and vomiting, which lasted five hours. When 1 year and 7 months old she had been operated on in Liverpool for "perforation of the bowel." In 1916 she was operated on by Mr. H. G. Cook at this hospital for peritonitis, the cause of which was not determined, but the appendix was removed.

When admitted she was pale and had an anxious expression. The pregnant uterus reached midway between the ensiform cartilage and the umbilicus. The abdomen was tender all over and was moderately rigid. My diagnosis was perforated gastric ulcer.

#### Operation.

At 4 p.m. on November 24th, twenty-four hours after the onset, the abdomen was opened by a long right paramedian incision. The pregnant uterus presented, and to its right side was a mass in the angle between the ascending and transverse colon, consisting of matted coils of ileum of a dark mulberry colour, beginning to lose their gloss and with a faecal smell. The mass was brought out, and it was found that there was a twist from right to left through 360 degrees, situated exactly at the ileo-caecal valve, where the gut was anemic. The proximal small intestine was moderately distended. A healthy portion was found; a clamp was applied there and also at the junction with the caecum; the ends were closed by a double basting suture over Parker-Kerr clamps. A lateral anastomosis was effected between the proximal intestine and the ascending colon, iso-peristaltic, by an inner Connell and outer Cushing suture. The mesenteric vessels were ligatured and the gap in the mesentery closed. The small intestine removed measured  $5\frac{1}{2}$  feet, and about 5 feet of this was gangrenous. The abdominal wound was closed without drainage; it opened a week later at the lower end and discharged pus freely for a time.

On November 26th she miscarried and was delivered of an anencephalic foetus. She then improved rapidly, the bowels being opened on November 27th; very persistent diarrhoea set in, which was difficult to control for several weeks, but at last ceased. She was discharged to a convalescent home early in January.

Kinking and twisting of isolated loops of small gut is not very uncommon as a cause of intestinal obstruction following the adhesions of peritonitis, whether due to appendicitis or other causes. Two cases are cited by Perrin and Lindsay, in the *British Journal of Surgery*, in their series of 400 cases of intussusception at the London Hospital, one being volvulus of the ileum, the other of ileum and caecum, following reduction; but such an extensive volvulus as this is, I think, unusual.

A lateral anastomosis, rather than an end-in-side, although taking longer to carry out, was thought to be the safer, as much less likely to leak; and the result appears to have justified this, as, in spite of infection of the abdominal wound from the gangrenous gut and the occurrence of very intractable diarrhoea, the patient made an uninterrupted recovery.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### MULTIPLE POLYPOSIS OF THE COLON.

At a meeting of the Royal Academy of Medicine in Ireland, reported in the *BRITISH MEDICAL JOURNAL* of January 3rd (p. 21), a paper was read by Sir W. de Courcy Wheeler on the condition known as polyposis of the colon, and interesting remarks were made as to its etiology and pathology. It was suggested that the polypi were the result of a chronic ulcerative colitis. The following cases in my experience throw an interesting light upon the etiology and show that in certain of these rare cases the cause is a congenital one.

When I was acting as house-surgeon in a London hospital a man was admitted, aged 30, who had for some years complained of the passage of bloody stools, and had lately been suffering from increasing constipation and rapid wasting. He was found to have a large fixed mass in the descending colon. It was decided to carry out complete removal, but he died on the second day after the operation. Upon opening the colon, the mucous surface was found thickly covered with small pedunculated polypi, and the malignant growth had evidently commenced in one of these.

About six months after I admitted his brother, aged about 32 years, with a similar history, and found a similar malignant growth in his left iliac fossa. In this case it was decided to perform colostomy; on opening the colon he was found to have a large number of pedunculated polypi of the same character as those found in the colon of his brother.

A third brother, aged 27, came to visit him while in hospital, and informed me that he frequently passed blood with his stools, but I had no opportunity of discovering whether the condition of his bowel resembled that of his brothers. He also told me that his mother died of cancer at an early age, and that his sister had died of carcinoma of the uterus at the age of 24.

Is it not probable that in these cases there was a family tendency to the formation of polypi upon the mucous surfaces and the malignant changes which are so usual in this condition of polyposis had taken place?

### CLINICAL AND SCIENTIFIC PROCEEDINGS.

#### OXFORD DIVISION.

The first meeting of the year of the Oxford Division was held at the Radcliffe Infirmary on January 28th, when Dr. NEILL presided over a gathering of about fifty members.

Miss BIGGAN, matron of the Radcliffe Infirmary, read a paper on the various diets used in the hospital, with special reference to that employed in the treatment of diabetes. The items were carefully considered from the point of view of the expense to the patient, and it was shown that the diet of a patient on an average amount of insulin cost rather less than that of a patient treated without insulin. Various forms of enemata and their uses were described and details given of the method of colon irrigation for diagnostic and therapeutic purposes.

Mr. HAYWARD PINCH gave a lecture on radium therapy, illustrated with lantern slides. The remarkable results of a single application of radium in conditions like rodent ulcer were well seen in the photographs. Other conditions treated with success included psoriasis, lupus, keloid, and naevi, and relief of symptoms and prolongation of life might be expected in epitheliomata, inoperable cases of lymphosarcomata, and Paget's disease of the nipple. In the time at his disposal Mr. Hayward Pinch was only able to deal with more or less superficial lesions.

Mr. GIMBLESTONE asked for a diagnosis in the case of a woman of middle age who came to the orthopaedic department with a patient and who was noticed to have altered nutrition of the finger-nails and wasting of some of the smaller muscles of the hands, and who complained of sensory changes in the fingers. Acroparesthesia and syringomyelia were suggested.

Dr. STOBIE showed a child, aged 19 months, who had been operated on twelve months previously by Mr. John Fraser of Edinburgh for hydrocephalus. At birth, which was uncomplicated, the child's head was of normal size, but when the baby was 4 months old the mother noticed that the eyes were peculiar and that the head was swelling. The latter increased rapidly in size until about six weeks before the child's admission to hospital, when it seemed to become fairly stationary. At that time the child was aged 9 months and looked well and bright. The head was uniformly enlarged, the sclera of both eyes showed prominently above the iris, the anterior fontanelle was bulging, and the pressure of the cerebro-spinal fluid was increased. The measurements of the head were: circumference 21 inches, vertical  $13\frac{3}{4}$  inches. The result of investigations made in hospital showed the hydrocephalus to be extraventricular in type, due to pre-natal adhesions between the edge of the tentorium and the peduncles of the brain. The common carotid arteries were ligatured at an interval of two weeks, and the baby was discharged with the fontanelle pressure greatly reduced. The present state of the child was eminently satisfactory. The fontanelle remained depressed, the head could be held up well, attempts to walk with assistance were being made, and intelligence and talking appeared normal.

Dr. SUMMERHAYES asked for opinions as to diagnosis and treatment in the case of a woman, aged 50, with a swelling in the left popliteal space of fourteen days' duration, associated with pain. The diagnosis suggested by the surgeons present was an affection of the "semi-membranosus bursa," and the treatment non-operative.

Mr. H. WHITELOCKE showed two cases: (1) A woman, aged 44, with a soft pedunculated tumour over the right eyebrow (noticed for the past thirty years) and a large mass of soft, non-adherent glands in the right preauricular and upper cervical region (present for eight years). It was agreed that a diagnosis could not be made until the tumour had been excised and examined microscopically. (2) A man, aged 59, epileptic, with recurrent dislocation of the right shoulder, to show the result of Clairmont's operation.

Dr. GIBSON showed a case of recurrence of symptoms of encephalitis lethargica of the Parkinsonian type in a boy of 15. The facies, attitude, and gait were typical; rigidity

was marked; tremors were absent. The boy was mentally normal; the only eye sign was a loss of the accommodation reflex. There was a tendency to sleep in the day and be awake at night. The sphincters were normal, and the only other nervous sign was an upgoing toe on the left side. He was being treated by hexamine and intravenous vaccine therapy, but the temperature still showed a tendency to rise for a few days from time to time.

### KENSINGTON DIVISION. LEGAL DISABILITIES IN THE EARLY TREATMENT OF MENTAL DISORDERS.

At a meeting of the Kensington Division of the British Medical Association on February 13th, with Dr. WALTER E. FRY in the chair, an address was given by Dr. R. H. COLE, physician in charge of mental diseases at St. Mary's Hospital, Paddington, on "The present legal disabilities in the early treatment of mental disorders."

#### Dr. R. H. Cole's Address.

Dr. Cole, after expressing his pleasure in the occasion, and mentioning that he had been a member of the British Medical Association for more than thirty years, said that legal restrictions were imposed in the treatment of various diseases, such as those of an infectious character, but in no department of medicine were these so paramount as in the case of mental disorders, when the liberty of the subject as involved. It was a question whether the legal encroachment in the domain of medicine had not gone so far as to constitute a serious menace to the State in the matter of the prevention and cure of insanity, which was admittedly the province of the medical man had been regarded as the authority on the treatment of diseases, although civilization onwards the Middle Ages were to some extent handed over to ecclesiastical folk and laymen. The appointment by statute of the Royal College of Physicians as the central body governing mad-houses in 1774 marked an epoch in medical supremacy, which subsequently led to a Government department being set up in the shape of the body now known as the Board of Control. He thought this body would be better recognized under a more suitable name, such as the "Board of Mental Health." "Board of Control" was used in connexion with liquor, railways, and other things; it was not sufficiently distinctive—people did not know exactly what it meant. This central authority, as now very properly affiliated to the Department of Public Health, under the Minister of Health, in place of the former Secretary, who presided over the Prison Service, was a notable advance and a sign of progress. He wanted to eliminate the idea of detention as much as possible. At present there was too much similarity between asylums and prisons, and the former were now being called mental hospitals. In the reign of George III, who himself suffered from mental illness, mental derangement in poor persons was the province of local justices of the peace, who frequently confined them to prisons, for lack of other accommodation. Permission to build asylums out of the rates only originated in 1808, and was not made compulsory until 1845. Medical certification was scarcely a written protection to the receiver of an insane patient until 1845. Matters indeed became regularized in 1884-5, when Lord Shaftesbury initiated his great work on behalf of the mentally afflicted. It seemed extraordinary that in recent times there had been no great public man who in any way approached the earnestness with which he undertook this work. As the result of repeated actions at law, the justices' order, which hitherto had been confined to the pauper class, was added to the private class in 1890, when the existing Lunacy Act came into operation, and the county councils took over the management of asylums from the justices. The close of the great war had directed popular attention more and more to the need of lunacy reform, which the medical profession had urged for so many years. The Royal Commission now sitting afforded a special opportunity for the profession's voice to be heard on this important matter.

The Medico-Psychological Association had devoted much attention thereto, and would shortly be presenting its evidence. As chairman of the committee concerned, he had spent a good deal of time over that evidence. A conference had taken place between representatives of that body and the British Medical Association; they had tried to agree on general principles, and in the main had done so. Every member of the British Medical Association must be grateful to its Council for the work it had undertaken through its special committee in the preparation of the important Memorandum of Evidence which was delivered by Dr. Langdon-Down and other witnesses before the Commission on January 14th (SUPPLEMENT, January 17th), and to which he wished to direct attention. The disabilities under which the profession laboured in the early treatment of mental disorders were obvious to all who had any experience. Directly a change from home was indicated in a patient who was certifiable, and was yet willing to accept treatment elsewhere, the requirement of certification existed to comply with the law. The stigma and consequences of certification were quite unequalled for in most temporary cases, or in the early stages of other cases of mental disorder, including those patients who were too ill to possess any volition at all. The law was in urgent need of amendment, so that clinics, with in-patient beds, might be established by the local authorities, and arrangements should be made for the provision of wards or annexes in the general hospitals. The rate-supported mental hospitals also should be available for the admission of patients on a voluntary basis, which would do much to remove the dissatisfaction attaching to detention in those institutions. The reputation of a place was altered very much by the presence of voluntary patients; it helped the certified patients if they knew that some of the others were not compelled to remain. Mental disorders should be regarded as a matter of health, and the Poor Law should have nothing whatever to do with them. The Mental Treatment Bill of 1923 would do much in the desired directions, even if the delay in the abolition of the Poor Law continued. As regards the paying class, it should be made legal for a certifiable patient, if harmless to himself or others, and not unwilling, to be treated temporarily in a nursing home or elsewhere that was recommended for him or her. By this means certification might be delayed or be entirely dispensed with, to the satisfaction of all concerned. At present the medical profession was unable to advise what was best for a patient by reason of the hampering state of the law, and many patients received no treatment at all and lapsed into chronic insanity which might have been prevented. A patient might be certifiable one day and not the next, or perhaps certifiable for a week and then recover; and to have two separate authorities seemed to him (the lecturer) entirely wrong. Dr. Cole went on to say that the medical members of the Board of Control were not sufficiently well paid. The salaries were fixed by Act of Parliament at £1,500 a year when the Board was initiated in 1845 and remained the same to-day. He had no axe to grind, but thought the remuneration should be about £2,500 a year. An unsatisfactory thing about the Board of Control was that the legal element was too much in evidence. It should be a medical body, with legal advisers. The address proceeded with an elaboration of some of the details specified in the British Medical Association's Memorandum, Dr. Cole remarking that it deserved the careful attention of the medical practitioner. It was so important that he wished it had been incorporated in the body of the JOURNAL; he was afraid too many busy practitioners did not give the SUPPLEMENT the attention it should receive.

#### Discussion.

The CHAIRMAN thanked Dr. Cole for his address and invited discussion. He said that the question of the salary of the members of the Board of Control, the suggestion in regard to voluntary boarders, and other points raised by Dr. Cole, were of very great importance.

Dr. CHRISTINE MURRELL suggested that voluntary boarders who were certifiable should be under the control of the Board of Control or some other body, otherwise they would not be adequately protected. The conditions in some of the asylums which the Board of Control would pass were

unsatisfactory—for example, patients quite well aware of their position were placed in the same ward with people who were moaning and yelling and unpleasant in their habits. There was no woman doctor on the Board of Control because the authorities refused to pay women the same as men.

Mr. E. B. TURNER, referring to the objection of practitioners to certify patients, said he had not certified one for thirty years. He was much impressed by the evidence the British Medical Association had put before the Royal Commission. It was exceedingly well balanced and well considered, and he agreed with all the conclusions.

Dr. MARY BARKAS considered that one of the two certifying doctors should be the patient's medical man. In view of public feeling, it might be well that an expert, as well as the judicial authority concerned, should be a party to the detention certificate. She saw no means of compelling local authorities to make adequate provision for early treatment unless the Board of Control had compulsory powers.

Dr. COLE, replying to the discussion, said the Board of Control had absolute powers over licensed houses and rented hospitals. The Medico-Psychological Association proposed that the Government grant should be payable to local authorities throughout the country on the certificate of the Board of Control. From the humanitarian point of view, he urged that there should not be too great differentiation between cases of chronic lunacy and acute mental disorder. He hoped that the British Medical Association's Memorandum would mark the beginning of a new era.

## Reports of Societies.

### VITAMIN DEFICIENCY AND ITS EFFECT ON HEALTH.

A SPECIAL discussion on non-specific disturbances of health due to vitamin deficiency was opened at a meeting of the Royal Society of Medicine on February 16th. The PRESIDENT (Sir St. Clair Thomson) was in the chair. The whole of the time was occupied by four opening papers, and when the question was put from the chair whether the general discussion should be resumed the same evening, after a short adjournment, only ten hands were held up in favour of this course. It was decided, therefore, that the discussion should be resumed at a later date, by which time members would have the advantage of seeing in printed form the papers which had been read, and which, as the President and Dr. William Hunter stated in some complimentary remarks at the close, together constituted one of the most remarkable contributions to the subject of vitamins hitherto made.

#### *Accessory Food Factors in General.*

Dr. LEONARD WILLIAMS, in a general survey of the whole question, said that a very superficial study brought one face to face with the impossibility of putting a vitamin in a water-tight compartment. The vitamin was not an entity, it was a subtlety; it could not be considered alone, it must be considered in relation to certain other things lying outside the orthodox trinity of fat-soluble A, water-soluble B, and antiscorbutic C. The first of the supplemental substances were the mineral salts. If the mineral salts in the dietary were present in adequate amount or were properly balanced, the absence or the deficiency of vitamins commonly so called mattered very little. Here he quoted at length from Dr. John Boyd Orr's paper in the *BRITISH MEDICAL JOURNAL* of September 20th, 1924 (p. 504), and then went on to ask where these essential mineral salts were to be obtained in their proper balance if not from untampered vegetable products. Then there were the catalysts, which effected chemical changes without themselves taking part in such changes. These were described by the late Sir William Bayliss, and a study of his work suggested that catalysts as found in the untampered state were essential to the utilization, not only of mineral salts, but of proteins, fats, and carbohydrates. Further, the paramount importance of friendly bacteria had to be

recognized, for it was only these which produced the enzymes. And where were catalysts or enzymes to be obtained except from Nature's laboratory? Chlorophyll also had to be reckoned with. All life depended upon chlorophyll, and it was by the vegetable kingdom alone that this was manufactured. Just as properly balanced mineral salts had been shown to be an adequate substitute for vitamins, so had sunshine. Sunshine played the essential part in germinating grain—in converting a body which was to all appearances dead and devoid of vitamins into a substance which was bursting with them. Finally there was the question—a very dangerous one to touch on at that moment, and especially in that hall—of electricity. Mineral salts were electrolytes, colloids had an electrical discharge, enzymes were colloids. These were facts concerning which there was no dispute. He pleaded therefore for the inclusion within the ambit of vitamins of mineral salts, catalysts, enzymes, chlorophyll, violet rays, and electricity. Each and every one of these was completely destroyed by heat, or at least was so profoundly altered thereby as to be no longer recognizable as a product of Nature's laboratory. It was these which constituted the power of resistance of the body to devitalizing influences. All disease, whether microbial or metabolic, was what mathematicians called a "function" of cookery and concentration. He was not a vegetarian, even in theory, although he had been accused of living on raw carrots alone. All that he did was to advocate the obvious—namely, that the forces and substances which he had mentioned must be represented in the diet, and could not be adequately represented or balanced so long as people failed to recognize that raw fruits and raw vegetables were essential. Not vitamins alone, but the other things which acted in conjunction with vitamins, and without which vitamins were powerless, must be taken into account. These other things were like the berries on the mistletoe, and he did not need to remind them that "it's the berries as does it."

#### *Disturbances of the Gastro-intestinal Tract.*

Lieut.-Colonel R. McCannism spoke of the effects of vitamin deficiency on the gastro-intestinal tract, and drew attention to the results of some experiments on monkeys which he carried out six years ago (*BRITISH MEDICAL JOURNAL*, 1919, i, 177, and ii, 36). These experiments led him to suggest that vitamin deficiency in food was an important factor in the causation of a number of the gastro-intestinal disorders so common at the present day, including irregular action of the bowels, whether in the direction of intestinal fluxes or of constipation, infection of the gastro-intestinal tract, chronic digestive disturbances with impaired absorption and assimilation of food, gastro-intestinal stasis, mucous disease in children, and colitis in adults. He prefaced his account of these experiments by three remarks: (1) that vitamin deficiency of lesser degree when protracted over longer periods of time might give rise to effects similar to vitamin deficiency of greater degree over a shorter time, although death in the former case, to judge from the animal experiments, was not usually from acute vitamin starvation, but from some intercurrent infection; (2) that there was an extraordinary variation in individual idiosyncrasy among animals of the same species and age to chronic vitamin starvation; and (3) that the results of such experiments as he had to bring before the meeting varied with the animals used and with the pathogenic flora of the intestine. The animals employed in these experiments were monkeys which, up to a few days before, were living their natural life in the jungles of Madras. A number of them were used as controls, and were given a varied diet with abundance of vitamins; the others were given the same diet after it had been subjected to a sufficient degree of heat in the autoclave to reduce its vitamin value very markedly. Some of these latter were given an item of fresh food to ensure a sufficient supply of vitamin C, or two items to ensure a sufficient supply of vitamin C and vitamin A; the food of all was deficient in vitamin B. The control animals remained in good health, the health of the others soon showed signs of impairment, one of the earliest and most constant symptoms being diarrhoea, with or without mucus and blood in the stools. Nine out of the

eleven animals treated in this way exhibited a severe intestinal flux. Five of the animals suffered from dysentery, and it seemed evident, after examination of the controls also, that many of the animals had been "carriers" of the organism of amoebic dysentery when the experiment commenced, and that the amoeba had remained harmless to the well fed animals, while it had attacked those whose food was deficient in vitamins. The first effect of such deficiency appeared to be to render the intestinal tract susceptible to invasion by bacterial or protozoan agents. It rendered pathogenic to the ill fed host organisms that might be non-pathogenic to the well fed. The monkeys survived from fifty-one to a hundred days. He described and illustrated the pathological changes discovered on opening the tract. The gross anatomical lesions included enlargement of the mesenteric glands, dilatation of the stomach, congestion of the gastro-intestinal tract, with ballooning of various parts, and marked thinning of the muscular walls of the colon. In the colon the changes were found to consist in greater or lesser degrees of colitis, which was the most marked and one of the most constant of the morbid changes present. He also described the changes found in various parts of the tract on histological examination, and went on to say that not all the changes were present in all the deficiently fed animals; in general they were more pronounced and frequent in animals whose food was deficient in vitamin A as well as in vitamin B, but each individual was more or less a law unto himself in regard to the effects of vitamin want. He touched on the work of Cramer and of Gross on rats fed on synthetic diets, and described the very recent work of Pappenheimer and Larimore, who had recorded the occurrence of gastric lesions in 55 per cent. of rats fed on synthetic diets in which the only known deficiency was want of vitamin A. He claimed, in conclusion, that derangements in function of the gastro-intestinal tract, and its greatly increased susceptibility to attacks by bacterial and other pathogenic agents, which had been shown to result from vitamin deficiency in monkeys and rats, was to be regarded as an important factor in the causation of the common intestinal disorders of mankind.

#### *General Experimental and Pathological Aspects.*

Dr. W. CRAMER urged that there was no fundamental distinction between specific and non-specific impairments of health due to vitamin deficiencies. The so-called specific deficiency diseases were merely the last links in a chain of events of which the so-called non-specific impairments were the earlier ones. When vitamins were withheld from the diet there ensued loss of appetite, constipation, diminished nitrogen retention, progressive atrophy of the lymphoid tissue, and other disturbances. He likened the action of vitamin B to that of the hormones as having a specific stimulus the absence of which led to atrophic changes. A striking feature in mammals suffering from vitamin B deficiency, even in its most advanced stages, was the absence of spontaneous infections, though in the case of experimental infections produced by injections of bacteria subcutaneously the resistance was said to be diminished in subjects suffering from vitamin B deficiency. Animals with vitamin A deficiency presented exactly the reverse condition: they always developed spontaneous infections, beginning in the mucous membranes of the intestinal and respiratory tracts and in the eye, although the general defences of these animals remained unimpaired until long after the local infections were established. The same diminished resistance to local infections had been observed in children, where xerophthalmia was always accompanied by, and sometimes preceded by, an infection, usually of the lungs. When, in badly nourished children, general infections occurred, such as pneumonia and enteritis, these were just as much specific deficiency diseases as the xerophthalmia. The speaker drew attention to the condition of "vitamin underfeeding," where the intake of vitamins was sufficient to enable the animals to grow and reproduce themselves, but where, nevertheless, health was impaired without any obvious symptoms of disease, as compared with animals receiving a more abundant supply of vitamins. He pointed out the harmful effect of vitamin underfeeding in pregnancy. It was frequently asserted that a civilized

community living on a freely chosen mixed diet was in no danger of suffering from a deficient vitamin intake. This was scarcely borne out by the work of Blegvad and Widmark in Denmark, whose population, owing to economic factors, had suffered from an extensive vitamin deficiency, shown by the decreasing consumption of milk and the increasing consumption of margarine. But similar conditions existed in this country, where the poorer classes, owing to their consumption of margarine, which was free from vitamin A, and of white bread, which was free from vitamin B, were cut off from some great natural supplies of vitamins. He believed that the wide extent to which this affected the health of the community was not at present recognized, partly because it was generally held and endorsed by leading authorities that the supply of vitamins was bound to be adequate if there were no specific deficiency diseases. This was an error, and the speaker maintained, on the contrary, that the organism, especially the young organism, which required for its full functional development an abundant supply of vitamins, suffered manifold disturbances of function with any degree of restriction of the vitamin intake.

#### *Bone Marrow Changes.*

Dr. G. M. FINDLAY referred in particular to the condition of the leucoblastic tissues, more especially those concerned with the formation of polymorphonuclear leucocytes, in connexion with the breakdown of the defence mechanism of the body following upon vitamin want. In animals fed on diets deficient in vitamin A it was rare to find lesions in the leucoblastic bone marrow, and correlated with this absence of degeneration in the marrow was the fact that there was no reduction in the number of leucocytes in the blood stream in this form of deficiency. In fact, after the onset of keratomalacia, it was not uncommon to meet with a polymorphonuclear leucocytosis. At the same time there was a fall in the bactericidal power of the blood which occurred in all acute infections. The infections associated with a deficiency of vitamin A in the diet were thus solely due to a local breakdown at the sites of infection—the conjunctiva and the epithelial lining of the respiratory and intestinal tracts. In animals fed on diets wholly deficient in vitamin B numerous small haemorrhages occurred in the bone marrow. When the diet was not wholly lacking in this vitamin a condition of gelatinous degeneration occurred in the bone marrow, with reduction in number of the leucoblastic cells. In acute vitamin B deficiencies there was a reduction in the total number of leucocytes in the blood stream, though this reduction affected only the lymphocytes. While the opsonic power of the blood and the capacity to form agglutinins, haemolysins, bacteriolysins, immune body, and antitoxin remained unimpaired, it was usual to find a fall in the bactericidal power of the blood in animals fed on diets deficient in vitamin B, which fall appeared to be correlated in some way with the fall in body temperature occurring as the result of diets lacking in this vitamin. Animals with reduced body temperature lost their resisting power to certain bacterial infections. Under normal conditions pigeons were totally immune to infection with the pneumococcus and meningococcus, but if their body temperatures were reduced to below 40° C., either by the action of some antipyretic drug or by feeding on a diet deficient in vitamin B, then the intraperitoneal injection of pneumococcus or meningococcus was followed by a fatal septicaemia. In the case of vitamin C, guinea-pigs with acute scurvy showed many small haemorrhages in the bone marrow. In chronic scurvy in this animal—a condition characterized by no definite clinical symptom—the bone marrow underwent either gelatinous degeneration or a fibrotic change which was not confined to the epiphyseal ends of the bones. If healthy guinea-pigs and guinea-pigs with chronic scurvy were given small intraperitoneal injections of organisms such as pneumococcus, *B. coli*, or staphylococcus, both groups survived, but when the number of such organisms was increased the animals with chronic scurvy died, while the controls survived. The increased susceptibility to infection occurring as a result of these vitamin deficiencies, however, did not apply to all bacteria, because diets lacking in vitamin did not modify the course of experimental tuberculosis in guinea-pigs or rabbits.

## SUBACUTE COMBINED DEGENERATION.

At a meeting of the Section of Neurology of the Royal Society of Medicine on February 12th a discussion was held on the etiology and treatment of subacute combined degeneration of the spinal cord.

Dr. A. F. HURST, in opening the discussion, emphasized the intimate association between Addisonian anaemia and subacute combined degeneration of the spinal cord. Three factors, he said, were to be considered in the pathogenesis—(1) achlorhydria, (2) oral streptococcal infection, and (3) duodenal streptococcal infection. The achlorhydria might in turn be constitutional or congenital, or secondary to lesions of the stomach such as atrophic gastritis, carcinoma, or occurring after gastro-enterostomy. The achlorhydria might be not only congenital, but he believed it was also often a familial condition. In the last event it was interesting to note the occasional familial incidence of Addison's anaemia and subacute combined degeneration. The factors concerned in the oral infection were pyorrhoia alveolaris, streptococcal infection of the jaws, tonsillitis, and the Hunterian glossitis. He especially emphasized the frequency of the glossitis, which he had almost invariably found since Hunter had called attention to this symptom. These two factors—oral infection and achlorhydria—led to a streptococcal infection of the duodenum. This resulted in the production of specific toxins which might be haemolytic or neurotoxic. In the first case anaemia of a particular kind was produced. He wished to remark on the diagnostic importance of two features in the blood picture, anisocytosis and megalocytosis, and referred to the work of Price-Jones and to the value of his charts. By means of his methods they had been enabled to make a diagnosis at a much earlier stage than was possible when chief reliance was placed on the high colour index or the percentage of haemoglobin. He stated that the anaemia present in subacute combined degeneration was always of the Addisonian type. He stressed the importance of prophylaxis, whereby persons who were found to be the subjects of a congenital achlorhydria might be prevented from developing Addisonian anaemia or subacute combined degeneration by taking sufficient dilute hydrochloric acid for the rest of their lives. In treatment he aimed at attacking the etiological factors as follows: the administration of hydrochloric acid for the achlorhydria; two drachms of the dilute acid were to be given in about twelve ounces of water three times daily, the first dose to be given in the morning on an empty stomach. Secondly, the removal of any foci of oral or pharyngeal sepsis. He said that such removal must be radical, but if the patient were seriously ill he advised a preliminary course of streptococcal vaccines. For the duodenal infection he used autogenous vaccines, and thought highly of the value of sour milk and charcoal as intestinal antiseptics. For the anaemia he gave arsenic, or in severe cases blood transfusions. Dr. Hurst's remarks were illustrated by several tables of great interest setting out statistics of cases of achlorhydria, Addisonian anaemia, and subacute combined degeneration.

Dr. MACBRIDE said that he and Dr. Carmichael had collected the records of 199 cases of subacute combined degeneration which had been in the National Hospital for the Paralyzed and Epileptic, Queen Square. In 53 of these the diagnosis was confirmed by autopsy. The average age at onset had been found to be 47½ years, the extremes being 26 and 70 years; 102 were males and 97 females. Heredity appeared to play no part in the etiology. No definite predisposing cause had been identified and no attacks of previous anaemia had been noted. In 78 per cent. of the cases the primary symptoms had been neurological, such as stiffness or numbness of the legs, while in the remaining 22 per cent. the primary symptoms could be referred to the anaemia. Alimentary symptoms were uncommon; 12 per cent. had been edematous, and 15 per cent. had been noted to have a sore tongue. In 14 cases free hydrochloric acid was found in the gastric juice by fractional analysis. A clinical resemblance to myxoedema had been observed in many cases, and some of these had taken large doses of thyroid extract, as much as 36 grains a day, without signs of thyroid intoxication. He thought that Dr. Hurst's theory of the essential importance of achlor-

hydria was untenable, and was inclined to think that some disturbance of endocrines was present. In treatment he had used arsenic, both by the mouth and by intravenous injections of novarsenobillon. He had not seen benefit follow the treatment of oral sepsis nor the exhibition of large doses of dilute hydrochloric acid. In none of the cases which they had studied had any change in the neurological signs taken place as the result of treatment.

Dr. WILLIAM HUSTEN thought that both pernicious anaemia and subacute combined degeneration were more common now than formerly. He wished to emphasize especially the infective lesions in these diseases, and particularly the glossitis, of which he showed many lantern slides demonstrating the conditions of the tongue and streptococci in the deeper parts of the tongue. There was a definite seasonal incidence for the onset and the recurrences of the anaemia—namely, about the months of July and August. He considered that the prognosis of the anaemia was better now than some years ago.

Dr. KNOTT spoke on the bacteriological flora of the duodenum in these cases, and said he had been impressed with the ease with which haemolytic streptococci could be found even in direct films. Recent experiments on rabbits had shown that a grave anaemia could be produced by feeding with haemolytic streptococci after the administration of alkalis.

Dr. COLLIER mentioned one case of subacute combined degeneration which occurred in a patient the subject of chronic lymphatic leukaemia. He thought that Dr. Hurst's teaching on one point was dangerous—namely, that patients with Addisonian anaemia who presented symptoms of numbness and tingling in the extremities were necessarily the subjects of subacute combined degeneration, or even bound to develop it later. He had himself never seen a typical case of pernicious anaemia go on to subacute combined degeneration of the cord. He had only seen one case definitely arrested by treatment, and that one had subsequently relapsed.

Dr. BARNES was unable to accept Dr. Hurst's views *in toto*. He alluded to the difficulties of clinical diagnosis. Out of twelve cases which he had examined lately by the methods advocated by Dr. Hurst, he thought that Dr. Hurst would have rejected nine as not filling the bill truly. One of these had an increase of hydrochloric acid in the gastric juice by fractional analysis. He thought that there might be different types of the disease, and had found in his experience that the cases which began with spastic signs tended to run a less acute course than those where signs of ataxia and gross defects of sensation were more prominent early signs.

Dr. ELLIS also thought that Dr. Hurst's views must be held to be non-proven, especially as to the pathogenicity of the streptococci. He related the details of a case of great interest where a man had a partial gastrectomy for a growth of the stomach (proved to be carcinoma on section) in 1909; now he presented the signs of subacute combined degeneration of the cord with a sore tongue, achlorhydria, and a blood picture suggestive of pernicious anaemia.

In a brief reply Dr. HURST maintained his own views, and said that he was unable to explain the statistics from the National Hospital.

## ETIOLOGY OF MINER'S NYSTAGMUS.

THE meeting of the Section of Ophthalmology of the Royal Society of Medicine on February 13th was devoted to a discussion on the etiology of miner's nystagmus. Sir ARNOLD LAWSON (President) was in the chair, and before the discussion started he alluded to the loss which ophthalmology had sustained in the death of Sir George Anderson Critchett. He said that as a colleague he would be remembered for his straightforward character, his unvarying courtesy, and his ready wit. Mr. ERNEST CLARKE also paid a tribute.

Dr. T. L. LLEWELLYN (Nottingham), in opening the discussion with some general considerations, said that miner's nystagmus was an occupational disease of the general nervous system, not merely a local disease confined to the ocular muscles. It affected chiefly coal-face workers, but

25 per cent. of all men employed underground—judging from an examination of large numbers of workmen—had some signs of the condition, and this reservoir of latent cases must always be borne in mind. The incidence of certified cases had risen sharply since the inclusion of miner's nystagmus in the schedule of industrial diseases, and especially since the broadening of the definition in 1913 and the difficult economic conditions of the post-war period. Deficient illumination of the coal-mine owing to the low candle-power of the lamps used and to the absorption of light by the coal was the chief factor in the production of the disease. Delay in dark adaptation and an increased retinal susceptibility were frequent symptoms. The determining influence of light conditions was evidenced by the greater prevalence of the disease in winter, the increased recovery rate in summer, and the onset of symptoms after dark. The disease was more prevalent in urban than in rural districts, and in some seams than in others. The depth of the workings and the thickness of the seams did not play so important a part as the age of the workman, the difficulty of working, the character of the shale, and the attention paid to the disease itself. He dwelt upon the importance of the personal factor, and upon the tendency of men suffering from illness or accident to attribute their incapacity to the onset of a nystagmus which they had had for years. The disease was often mimicked and readily brought on by suggestion. While most cases showed no evidence of a neurosis, a group of cases had certain neurotic symptoms associated with well marked signs of the disease, and in another group the neurosis was dominant and was accompanied by slight or indefinite symptoms of nystagmus. When a neurosis was present it differed in no way from the neurosis found in other conditions, and its treatment was the same. The provision of suitable work helped the recovery rate. Sufferers rapidly deteriorated if they were allowed to remain idle. High as were the figures for new cases in 1923, they were lower than in 1922, and he believed they would prove to be lower still in 1924. Colliery owners were now alive to the importance of prevention, and large sums were being expended on the provision of lamps giving larger candle-power.

#### *Physiological Consequences of Very Dim Illumination.*

Professor J. S. HALDANE thought that it might now be regarded as clearly established that miner's nystagmus was brought about by using the eyes for guidance in muscular movements when the absolute (not relative) differences in luminosity of the objects seen were extremely low. He did not propose to discuss the evidence in favour of this conclusion or against other theories as to the cause of miner's nystagmus, but only to draw attention to a certain physiological peculiarity of vision where the illumination was extremely feeble. It seemed to him that this peculiarity furnished a key to the understanding of how miner's nystagmus was produced. Within wide limits of illumination the acuity of vision was practically constant, but it began to fall off seriously with low illumination until, when the illumination was sufficiently low, it was not possible to distinguish a white or a black object. It was also well known that with good or even moderate illumination acuity of vision was much greater at the centre than at the periphery of the field of vision, but with very low illumination this was no longer the case. One great peculiarity of foveal vision, with sufficient luminosity, was that the impression on the consciousness of an object on which the eye was focused was a lasting one—the person continued to see it—whereas in the peripheral visual field objects were perceived and then faded out of consciousness. If the eyes, for instance, were focused steadily on a fairly bright star, the surrounding stars would fade out of the vision except those which were twinkling, but in the twinkling stars the twinkle—which was only a variation in luminosity—became enormously exaggerated. A twinkling star, seen in the periphery of the visual field, with the eye fixed, disappeared completely from vision during the intervals of the twinkling. With very low luminosity the foveal vision lost completely its lasting character, and the conscious impression was even less lasting than with peripheral vision. Therefore the eye, trying to focus on the object, wandered about, picking the object up momentarily with the fovea and losing it again.

In all probability the fatigue thus induced was the disturbance which led up to the condition of miner's nystagmus. The nystagmus might perhaps be regarded as a tendency to a bad habit brought about by the fact that with very low illumination the eye was always moving. With ordinary hand safety lamps in the mine the illumination of the working space was not only very low, but the actual luminosity was extremely low also. There was no nystagmus among those who worked in mines where oil cap-lamps were used, because with such lamps the illumination of the miner's working area was far greater. It seemed clear that unless the illumination was greatly increased either by the use of cap-lamps or by much more powerful hand lamps, nystagmus would continue to be prevalent among coal-miners in this country. The illumination required to prevent nystagmus was such as to permit of lasting foveal vision, and therefore of fixing the eye on the object seen. This fixation was necessary for the proper guidance of any tool the miner was using. To judge from a number of different observations, the threshold illumination below which lasting foveal vision became impossible varied considerably in different individuals. This might be related to varying liability to nystagmus. With the old-fashioned oil safety lamps about half the miners working on the coal face showed signs of nystagmus, though few of them had serious symptoms. Visual acuity was, of course, greatly affected by defects of accommodation. He did not think, however, that it was the falling off of visual acuity, but rather the greatly diminished lasting power of foveal vision which led to nystagmus. Professor Haldane added that as it was still believed by some that miner's nystagmus was due to gases in coal-mines, he would like to take the opportunity of saying that, so far as he could see, the action of abnormal gases could have nothing whatever to do with the causation.

#### *Quality of Illumination in Coal-mines.*

Mr. H. S. EBBWORTH (Ebbw Vale) said that what was needed in coal-mines was a better quality of illumination, not necessarily a higher candle-power. Attention was drawn to the importance of the quality of the light by observing that when an oil lamp was taken into a mine not only was the candle-power diminished, but the remaining light was changed in quality, being deprived of yellow and orange rays, and retaining only a pale-bluish illumination. In the case of the Marsaut safety lamp the percentages of red, green, and blue rays with the lamp at the surface were respectively 71, 22, and 7, and with the same lamp in the mine the figures were 69, 20, and 11; at the same time the candle-power diminished from 0.48 c.p. at the surface to 0.21 c.p. in the mine. He had experimented with yellow-tinted glasses, and had found it possible, with the Oldham lamp, to change the quality of the light so that instead of a proportion of blue rays amounting to 17 per cent. he got the proportion with the tinted glass down to 11 per cent., at the same time increasing the proportion of green rays from 31 per cent. to 38 per cent. But he still wanted the blue constituent in the Oldham lamp to be further reduced to be about 6 per cent., as in the carbon filament, where the proportions of red, green, and blue were respectively 67, 27, and 6 per cent., and an excellent quality of light was forthcoming, very much like that of a candle. The Ebbw Vale Company had used yellow-tinted glass for a year, and the result had been quite satisfactory, although the ideal quality, which was that of the carbon filament, was not yet attained, and the total amount of light was still below the minimum desirable. Because a lamp gave 1 c.p. at the surface it was useless to assume that it gave this to the collier at his working place; it gave him, in fact, very much less. The minimum of candle-power required to bring a steam-coal pit up to the level of safety was 0.9 c.p. But with this yellow-tinted glass the Ebbw Vale miners had suffered to a much less extent from nystagmus. Some of the worst cases of nystagmus had loss of central vision, and it seemed to him that this might be due to the focusing upon the eye for too long a period of ultra-violet rays from the lamp, thereby exhausting the visual purple or otherwise damaging the eye. The yellow-tinted glass acted as a filter to prevent ultra-violet radiation from emerging.

Later in the discussion Mr. G. J. SACUS pointed out that even with the clear glass of the lamp the ultra-violet rays would be practically cut out, and that lead glass of  $\frac{1}{2}$  mm. thickness would absolutely eliminate any dangerous rays.

#### Compensation in Miner's Nystagmus.

Professor E. L. COLLS (Cardiff) stated the view that the increased incidence of nystagmus was apparent rather than real. An increase in compensation claims had occurred owing to the disease being an occupational neurosis—that is, a complex of a physical symptom and an underlying neurasthenia. The physical symptom—oscillation of the eyeballs—was present, without causing inconvenience, in 20 to 30 per cent. of miners working in poor illumination. In Belgium incapacity for nystagmus soon terminated, and the limit of time for which compensation was payable was six months. In this country the period of compensation was not limited. When the disease was so scheduled that a claim could be maintained on neurasthenic symptoms alone, the number of claims, particularly those of old standing, rose. In 1921 there were 1,913 new cases, and the continued cases on the books were 4,804, of which 645 had lasted for over five years, and 89 of these for over ten years. When economic factors in 1922 and 1923 brought possible earnings and compensation payments somewhat close together, and there was also a fear of unemployment, a still greater rise in the number of claims occurred. The course of events was similar for claims on account of miner's beat-knee and beat-hand (septic infections) and non-fatal accidents, but in the case of fatal accidents no increase took place—a fairly certain indication that no real increase in non-fatal cases had occurred, but that the increase in claims was due to economic factors. The excessive rise in old standing claims of nystagmus, which were nearly all based on neurasthenic symptoms, with no oscillation of the eyeballs, supported this contention.

#### Colliery Administrative Experience.

Mr. G. J. BINNS (managing director of the Midland Colliery Owners' Mutual Indemnity Company) said that it must be assumed that a very large number of cases which went down as nystagmus were not really nystagmus. Certifying surgeons were naturally not experts in nystagmus, and many colliery proprietors did not take steps to check the certificates. He gave an account of appeals which had been made by his company in 32 (out of a total of 428) claims on account of nystagmus, and of that 32 the company had won 28. Someone had said that nystagmus was caused through too much attention being paid to it. He did not subscribe to this, but he felt that the condition was one which needed the right kind of attention, sympathetic and skilful, not the kind which consisted in saying to the man, in effect, "You will go blind if you go down the pit again." The Under-Secretary for the Home Department in the last (the Labour) Government (Mr. Rhys Davies) had stated that the Home Office was prepared to amend the definition of nystagmus if colliery owners would guarantee to find light work for nystagmus patients. It was very difficult, however, to find surface work for men thus disabled.

Mr. H. MITTON (mining engineer to the Butterley Colliery Company) gave figures for eight collieries employing 7,000 men underground. The incidence of (certifiable) miner's nystagmus in 1924 was 0.56 per cent., and in 1913 it was 0.95 per cent. He attributed the decrease to the improvement of illumination.

#### Effect of Mine Gases.

Dr. F. RONSON (Penarth) gave figures from 1908 onwards to show that nystagmus was growing. The numbers now were getting huge. The whole coalfield had been seriously affected. This was not a condition which could be put down to neurasthenia. The increased knowledge of coal as a result of the work of the coal chemist had helped the clinician to visualize the possible relationship of coal to neurological disturbance. The miners among whom nystagmus was mostly found were those working on bituminous coal, and it seemed to be a fair inference that the high incidence of nystagmus was associated with certain compounds of coal which were to be found specially in the bituminous variety. Coal of this kind had also the highest

percentage of volatile matter. He pointed out further that nystagmus did not affect miners in other minerals, no matter at what depth they worked nor what kind of lamps they used. Nystagmus was an affliction of the coal-fields. He believed that the proportion of volatile matter yielded by coal might play an important part in causation.

#### The Personal Factor.

Mr. G. H. POOLEY (Sheffield) said that the personal factor was of two kinds—that of the observer and that of the person observed. In the case of the observer the personal factor entered to a great extent. Some men formed a theory and then looked for facts to support it. The incidence of the disease could only be determined by the examination of a number of men working in a particular mine, and as far as possible under the actual conditions of their work, and then discovering what percentage of them had got the disease and the degree to which they had got it. He had been carrying out some experiments to discover what the normal eye could see at an illumination of 0.00006 c.p. At that very dim illumination the normal eye could still detect colour; there was a visual acuity of about  $\frac{1}{72}$  of the normal. A good deal of flicker was experienced, fatigue was very marked, and a moving object was more readily seen than a stationary one. The colour best seen was red, green was detected less readily, and blue and yellow less readily still. The eye was so readily fatigued in the dim light and retained fixation so badly that there was no doubt a tendency, even in the case of the healthy eye, to oscillate under such conditions. He laid stress upon the point that a man was able to work in spite of a very marked degree of oscillation. Men whose eyes were never still, and who had a definite undulatory oscillation of their eyes, could still not only go on getting coal regularly and steadily, but in many cases could play cricket in quite good teams. With extremely little sight men could earn full wages at the coal face. Many of the men who went on compensation for nystagmus were suffering from quite other ailments, but found it to their monetary advantage to go on workmen's compensation for nystagmus rather than on sickness benefit under the National Insurance Act. A good deal of the so-called neurasthenia was a *maladie imaginaire*.

The discussion ended on this question of the personal factor. Dr. M. CULPIN said that nystagmus *per se* did not disable. The photophobia, the head tremors, the extreme convergence of the eyes, and the night blindness were all seen among the mental results of the shocks and stresses of the war. Everyone knew by now the kind of man who fell a victim to these troubles. There was an epidemic of night blindness among soldiers. The cases should be treated for the neurasthenia, and it would disappear and with it the nystagmus. Dr. C. F. HAUFORD drew a parallel between shell shock and nystagmus, and said that search must be made beyond the factors of illumination, or posture, or refractive errors; the personal element—the moral—must be considered. Dr. H. W. EDMISON also considered that a strong psycho-neurotic element was an etiological factor. He commented upon the fact that many cases experienced an acute exacerbation on examination or when attention was directed to their condition.

#### ANAL AND RECTAL FISTULAE.

At a meeting of the Section of Surgery (Subsection of Proctology) of the Royal Society of Medicine on February 12th, with Mr. F. SWINFORD EDWARDS (President) in the chair, a discussion took place on the subject of fistulae.

The PRESIDENT said that he looked upon the treatment of fistula as a specialty within a specialty. He had come across most excellent proctologists in every other respect who yet failed miserably when dealing with fistula of the horseshoe type. Of all the lesions which the proctologist was called upon to treat none would tax his powers more heavily. It took years of experience for a man to become thoroughly familiar with fistula of the horseshoe variety—a form encountered much more frequently than was generally supposed. The reasons for the frequent failure of operative interference were the lack of topographical knowledge of the particular case, with a failure to lay open the whole

track or tracks; the non-recognition of fistula due to caries of the coccyx or the lodgement of a foreign body in a sinus which the surgeon had failed to lay open; the special difficulties attaching to tuberculous fistula; omission to remove all overhanging margins of skin and mucous membrane; injudicious after-treatment, such as painful and too frequent dressings and over-long confinement to bed. To those about to operate for fistula he urged a careful examination by palpation; a probe was rarely necessary. To the external orifice was behind an imaginary line drawn transversely across the centre of the anus the internal orifice would be found usually as a depression between the two sphincters in the mid-dorsal line, and this pointed to a horseshoe or semi-horseshoe fistula. When dealing with a sinus which might run up at right angles; this must on no account be laid open into the bowel. It was a curious fact that where a horseshoe fistula had two internal openings, the lower one between the sphincters was to be felt as a depression, whilst the upper one projected into the rectum and felt like a small wart or papilla. He emphasized the importance of the two-stage operation; the first procedure was to lay open all tracks into the main posterior sinus, and then, after three or five weeks, when the wounds were healed, a slight secondary operation, dividing the external sinus, which, of course, included the main sphincter, completed the cure. With regard to exsection with immediate suture, he had tried this in only two cases, neither case did he get complete primary union. The shorter convalescence hardly compensated for the additional risk involved, and he could see no reason for supplementing the old method of healing by granulation. The secret of success in operating on horseshoe fistula was the antero-posterior dorsal incision.

Sir CHARLES GORDON-WATSON, who mentioned that at St. Mark's the average number of fistula operations was 150 a year, said that with regard to tuberculous fistula the textbooks were apt to mislead the practitioner by implying that this was a hopeless condition. Many fistulae were tuberculous without the patient being tuberculous. Of course, where the body was involved, a tuberculous or other parts of the body were invaded with tubercle the mere fact that his fistula was invaded with tubercle bacillus was no barrier to a cure, given correct surgery and after-treatment. With regard to the posterior track up the bowel resulting in a secondary opening in the horseshoe fistula, he had hesitated long as to proper treatment. It was a most dangerous thing to open up completely into the bowel. The majority of these tracks were submucous, but when they were not submucous and were very high up. He had once or twice been bold enough to slice into the bowel, and he did not think there had been ultimate incontinence, although there had certainly been temporary incontinence. With regard to primary suture, he thought that this question had been influenced by experience in the war, when a great amount of work of a very important character was done. At one period in the war a certain number of beds at one of the casualty clearing stations were set apart solely for the purpose of investigation in connection with primary suture of wounds, and he thought that something had been learnt about primary suture in consequence, and that better results were now forthcoming than could have been obtained without that experience. In the case of a direct fistula an excellent result could be obtained by primary suture, and the convalescence considerably shortened. A little while ago he brought forward a series of seventeen cases of primary suture; the results were all exceedingly good, with a high average of primary union. Some were done by excision and primary suture treatment with bismuth and iodoform paste. Nevertheless, the indiscriminate use of this method was very dangerous. If it became a routine it would lead to disasters, and its proper use required a considerable experience of cases and an ability carefully to select them. He had found Finsen light stimulate sluggish lesions to heal.

Mr. W. E. MILES said that the average general surgeon did not realize that there were more types of fistula than one. The ordinary textbook would speak of fistula as having the following varieties: a complete fistula consisting of an external opening on the skin surface, an internal opening into the rectum or anal canal, and an intermediate sinus or track; a blind external fistula, and a bilateral internal opening; a blind internal fistula, with no fistula. That was all very well in its way, but it did not throw much light on the subject. They all knew that a fistula was preceded by an abscess, and the track of the found in four chief positions: the subcutaneous abscess, the submucous abscess, the ischio-rectal abscess, and the pelvic-rectal abscess. Each of these abscesses, and the pelvis of the varieties to which he had just alluded. There might be a complete subcutaneous fistula or a subcutaneous fistula with a single opening, and when it was opened up one found an ischio-rectal abscess, and so forth. Very often one found an ischio-rectal abscess, and when it was opened up one found a fistula behind it. Some surgeons would say that a fistula whose internal opening was at a level of two or three inches above the anal verge might be laid open with impunity, whereas other surgeons would say, with equal truth, that it was a most dangerous thing to do, and that if one laid open such a fistula according to textbook instructions most disastrous consequences would ensue. Here were two opposite views which it was hard to reconcile, but both were right and both wrong. In the one case what was being spoken of was the submucous fistula entirely, and in the other case the pelvi-rectal fistula.

Mr. ASLETT BALDWIN favoured ionization treatment in some cases. With a callous surface which would not heal, no matter whether the positive pole, was very effective.

Mr. IVOR BACK said that he was inclined to classify the varieties as three: a fistula with an internal opening, which was always secondary to the opening between the two sphincters, and might be at any part of the anal canal or in the rectum; and a pelvi-rectal fistula, which last, to his mind, had nothing to do with the rectum whatever and was a primary indication of some disease higher up. With regard to deepest cut area one would, in a large proportion of cases, of straight fistula, get primary union.

Mr. L. E. C. NOBLE spoke of success in the treatment of tuberculous fistula; and Mr. SWINFORD EDWARDS, in a closing remark, expressed the view that pelvi-rectal abscess was very rare and was the result of gonorrhoeal prostaticitis, and, of course, the treatment must be extrarectal.

## TREATMENT OF PLACENTA PRAEVIA.

At a meeting of the Edinburgh Obstetrical Society held on January 14th, the President, Professor B. P. WATSON, in the chair, a discussion was held on the treatment of placenta praevia.

The PRESIDENT and Dr. DOUGLAS MILLER gave a statistical analysis of 254 cases of placenta praevia, of which most had occurred in the Edinburgh Royal Maternity Hospital. In 25 of the cases the mother died, representing a maternal mortality of 9.8 per cent. In explanation of the high mortality incidence it was stated that several of the high cases had been sent into hospital from long distances and the patient had arrived moribund from loss of blood. The causes of maternal death were as follows: Ante- and post-partum haemorrhage in 13 cases; sepsis, 6 cases; and one ileus, post-partum collapse and mania, eclampsia, duodenal partum haemorrhage, the last two patients dying undelivered. Including stillbirths and neo-natal deaths the foetal mortality was 64 per cent. In 81 cases the situation of the placenta was central, the maternal mortality being 22 per cent., and the foetal 82 per cent. The maternal mortality in the partial cases was 4 per cent. and the foetal 59 per cent. Consideration of the results of the different

than 50 per cent. of the cases; moreover, in a case reported by Dujardin-Beaumetz, in which there was almost complete closure of the superior vena cava resulting from compression of an aneurysm of the aorta, there was a continuous murmur. This, however, was not an important objection, because, as Professor Shennan pointed out, other cases in which a similar pathological change was present showed a somewhat different murmur. The diagnosis must be based upon a combination of physical signs, seeing that even the absence of a murmur might not weigh greatly in the scale against the diagnosis of a varicose aneurysm.

Mr. G. H. COLE mentioned the diagnostic relationship between this condition and dissecting aneurysm. He referred to the absence of laminated clot in the cases where the blood pressure must often be low, and in which von Recklinghausen's theory might be held to apply.

Mr. WILLIAM ANDERSON first referred to the work of Makins in traumatic arterio-venous fistulae, and mentioned particularly the delay of a few days in the appearance of symptoms after the injury. He then referred to the recent work of Holman, whose experiments seemed to show that the bruit and thrill in these cases was due to the vibration of the septum between the artery and vein, and could be made to disappear by simple closure of the vein proximal to the fistula, even though blood continued to pour through it towards the periphery. He also mentioned the increase in blood volume, the fall in blood pressure (systolic, and, more particularly and permanently, diastolic), the slowing of the pulse on compression of the artery, and the general effects on the whole organism of throwing out of use as much as a quarter or two-fifths of the total blood volume in these cases.

### THE UTERUS AS A CENTRE OF TOXINS AND IRRITATIVE PRODUCTS.

At the annual meeting of the North of England Obstetrical and Gynaecological Society, held at Manchester on January 16th, the retiring President, Professor A. DONALD, gave his valedictory address on the subject of the uterus as a centre of toxins and irritative products.

Professor Donald first discussed briefly the toxæmias of pregnancy and of the puerperium, with special reference to two conditions—namely, toxic liquor amnii and toxic lochia. He mentioned a case of acute urticaria which was undoubtedly due to changes in the liquor amnii, and also some cases of acute toxæmia commencing about the twelfth day of the puerperium, which were due to the accumulation of toxic lochia in a flabby uterus, the cavity of which was below the level of the cervix. He thought that there were cases in which these toxic elements, produced during abortion or confinement, might persist for a long time afterwards, and referred to a case of acute eczema which occurred some months after an abortion, and which resisted all treatment until the uterus was curetted; the eczema then rapidly and permanently vanished. He believed that in many cases the heart and the nervous system were functionally affected by these toxins, which might also play a part in causing rheumatic affections. Their origin was not only in the contents of the uterus, but sometimes in its substance. There were undoubted indications that fibroid tumours of the uterus were associated with a toxic condition in the patient; this was most noticeable when a fibroid was undergoing rapid diminution at the menopause. There seemed to be disintegration of the growth, and absorption of the products into the general system, attended by palpitation, profuse sweating, loss of flesh, and cachexia. The cases cited had occurred mostly in parous women, but he believed that they were sometimes seen in nulliparæ and virgins. The effects of some irritative products seemed to be purely local. Sometimes the conditions seemed to result from bacterial invasion, and at other times to be due entirely to chemical irritation, but it was not always easy to distinguish between them. The so-called senile vaginitis, and especially senile endometritis and pyometra, seemed to be caused by bacterial invasion. Pruritus might be due to the same cause, but also occurred in single women, in which case it seemed to be due often

to irritative elements in the menstrual discharge or to an irritating leucorrhœa. Another condition often due to irritation was dyspareunia. In the very severe cases there was probably a nervous or even a mental element, but in the more common type he believed that a uterine discharge which might be slight in amount kept up a condition of local irritability. His practice was to dilate and curette in these cases, and the results had been more satisfactory than after any other method of treatment. Finally, he thought that cervical erosion was in a great many cases the result of an irritating discharge from the uterine cavity. The general opinion seemed to be that it spread from below, and many seemed to think that it was most commonly caused by gonorrhœa, but Professor Donald believed that this cause was greatly exaggerated. This irritation might appear after a confinement, but it was not uncommon in virgins. The teaching was generally that it was purely cervical in origin, but there were good grounds for believing that it was caused by the discharge from the uterus. In all cases of cervical erosion, except where there were reasons to believe that it was the result of gonorrhœa, the cavity of the uterus should be curetted. It was not uncommon in these cases to remove by the enrette large masses of glandular tissue. A condition which seemed to him to prove the irritative effect of the intrauterine discharge was the so-called erosion of the posterior lip in cases of retroversion. The erosion was not confined to the posterior lip, as could be recognized when the uterus was straightened by a vulsellum, but it was chiefly situated there because the intrauterine discharge, owing to the position of the uterus, was obliged to flow over the posterior lip of the cervix.

#### Pelvic Adenomyoma.

The PRESIDENT opened the discussion on Dr. Kenneth Bailey's paper, which was read at the last meeting of the society on December 19th, 1924, and reported in our issue of January 24th, 1925 (p. 165).

Mr. GORAN thought that the cell implantation explained most satisfactorily many cases previously difficult to understand. He thought, however, there was still room for Cullen's mucosal theory and for the theory of development from Müllerian rests. He referred to a case recently seen by him in which a tumour over the left pubic spine became swollen and painful at each menstrual period, and at operation proved to be an adenomyoma of the round ligament. There was no evidence of any intrapelvic disease and no hernial sac, so this tumour could not be accounted for by the implantation theory.

Mrs. BARTON HALL doubted whether retrograde menstruation was a pathological process as Dr. Bailey had suggested, and was associated with other pathological changes, including an increase in the loss of surface epithelium; she asked why this actively invading epithelium did not embed itself in the wall of the vagina.

Professor FOTHERGILL raised the question whether menstrual back flow was an isolated occurrence or took place repeatedly in certain women.

Miss IVERS said that she had been able to excise localized uterine adenomyomata in one or two cases without removing the uterus.

Dr. D. DOUGAL thought that the evidence in favour of the Fallopian type of growth was not very convincing. The theory appeared to rest chiefly on the fact that the cells in these cases were ciliated, but the uterine cavity was also lined by ciliated epithelium and he could not understand why menstrual hæmorrhage should be associated with the activity of tubal epithelium. Retrograde menstruation appeared to furnish the most reasonable explanation of how the implants reached the peritoneal cavity. Adenomyoma had been found in certain situations difficult to explain on this theory, but he thought that all of them could be so explained. He referred to the successful experiments in rabbits by Victor Jacobson which proved that endometrial transplants in the peritoneal cavity were capable of active growth in the new situation. Clinical observations also supported this. Sampson had referred to four cases where adenomyoma occurred in the abdominal scar after operation on the pelvic organs, and Loehraue had also reported a case. Accepting the endometrial origin of these tumours as proved, and retrograde menstruation as the process by

which the implants reached the peritoneal cavity, certain other problems remained for solution. Was retrograde menstruation a frequent occurrence? What conditions of the uterus predisposed to it? The association of fibroids with adenomyoma had been frequently noted. Dr. Dougal referred to the confusion with regard to the nomenclature of this condition, and did not think Dr. Bailey had improved matters by suggesting another name. He thought the terms "endometrioma" and "endometriomyoma" suggested by Blair Bell were the best so far.

Professor BLAIR BELL was unavoidably absent, and Dr. Hendry accordingly read his remarks. Professor Blair Bell had been present as a guest of the American Gynecological Society on the historic occasion when Sampson read the first communication in which he demonstrated the endometrial character of the elements which were found in the ovaries in the circumstances under consideration. When Professor Blair Bell returned home he discovered endometrium in the ovaries in a case of bilateral "tarry cysts," and this was the first case demonstrated and published in this country. He knew of no inherent reason why there should not be two types of ectopic gland-bearing tissue, one endometrial and the other of tubal origin, but only the endometriomata had any practical or clinical interest, for menstruation could not occur in connexion with tubal glandular tissue. He thought that Dr. Bailey might be in error in describing the line of epithelium which he had illustrated on the surface of one ovary as tubal; it resembled germinal epithelium. Professor Blair Bell held that in certain cases the "cellular spill and implantation theory" of Sampson could not apply. For instance, endometriomyoma of the round ligament in the inguinal canal—a case of which he had recently reported to the society—could not originate in this way. Such a tumour was congenital in nature, the primitive endometrial tissue having been displaced by the external muscular coat of the uterus in the process of development. He believed that endometriomata were both developmental and implantational in origin.

In Dr. LEITH MURRAY's absence, Dr. Hendry read his remarks also. Dr. Leith Murray emphasized the need for keeping an open mind about the pathology, more particularly in view of the adhesions which occurred at certain sites, and the association in some cases of "adenomyoma" of the Fallopian tubes with the tubercle bacillus. He would like to know to what extent bilateral oophorectomy influenced these ectopic growths when occurring in the rectovaginal space.

Dr. BAILEY, in his reply, referred to mistakes made in the past as to the nature of this condition and to the views held with regard to the amount of epithelium lost from the endometrium during menstruation; he believed that a considerable quantity was cast off into the uterine cavity during menstruation. The vaginal wall was often invaded to a certain extent by small nodules of growth. He had never found any trace of bacterial infection in these growths, and cultures from the "chocolate" fluid blood were always sterile. He had never encountered a case exhibiting malignant change. He insisted that the invasion of the ovary by the growth resulted in the production of a cavity without any evidence of the formation of a cyst wall. He therefore thought that the term "tarry cyst" was wrong, and that "ovarian blood cavities" or "menstrual blood cavities of the ovary" should be substituted. The "site of rupture," he held, was merely the original site of implantation. He believed that the invading elements were deposited probably at every menstrual period in some women, but did not necessarily invade at every deposition. He also believed that retrograde menstruation was of regular occurrence and that it might be one of the main factors in the causation of dysmenorrhoea in young women.

Dr. DOUGAL showed a specimen of a very large "tarry cyst" of the ovary.

At operation on a married woman 30 years of age, who had never been pregnant, the tumours shown were removed. The larger tumour was seen to arise from the right ovary, being quite free from adhesions, except on the posterior aspect of the broad ligament, where it was firmly attached over a large area. On puncturing the cyst wall with a trocar, tarry or chocolate-coloured contents escaped. The cyst measured about ten inches in diameter, and had thin walls except where adherent to the broad ligament.

Its inner surface had no definite epithelial lining, but appeared to be composed of a striated layer of fibrin-like material; outside this the wall was composed of compressed ovarian tissue. Further exploration of the pelvis showed another cyst occupying the position of the left ovary. It was adherent to the back of the uterus and left broad ligament, and was about the size of a Tangerine orange. It also contained a tarry fluid, and adenomatous tissue was found at the inner pole in the neighbourhood of the ovarian ligament.

The chief interest lay in the size of the larger tumour, the contents of which measured about two pints. It seemed extraordinary that such a quantity of blood should be poured out as the result of functional activity of implanted endometrial tissue. It might be suggested that the haemorrhage resulted from interference with the blood supply of the tumour, but there was no evidence of this. Tarry cysts varied much in size, but were rarely larger than a Tangerine orange. The largest one in Sampson's series of cases measured about five inches in diameter.

Professor W. E. FOTHERGILL showed a haematometra associated with absence of the vagina, double haematosalpinx, and ovarian blood cysts removed from a girl 11 years of age. When examined under an anaesthetic the vaginal orifice admitted only the tip of the little finger, and the urethra was a mere slit. Rectal examination showed a very large uterus. At the operation it was found that the vagina was only represented by a fibrous cord. Cases of haematometra associated with other developmental abnormalities were referred to by Mr. PHILLIPS, Dr. W. FLETCHER SHAW, Dr. R. A. HENDRY, and others.

Dr. J. W. BURNS read notes of a case of hydatidiform mole and chorion-epithelioma from the same patient.

The patient, 28 years of age, had had two children, the second four years ago, and was seen first on March 7th, 1924, complaining of swelling in the abdomen and bleeding. Her last menstrual period was on December 20th, 1923, and bleeding began on February 20th, 1924. Examination of the patient suggested the existence of a uterus pregnant about sixteen weeks with a cystic tumour on the left side. Under anaesthesia, on passing a finger high up into the cervix, the tumour on the left of the uterus disappeared and the swelling resembled a symmetrically enlarged uterus twenty to twenty-two weeks pregnant. The cervix was tightly packed with sterile gauze, and the patient returned to bed. Two days later a hydatidiform mole was delivered, weighing 20 ounces, and a few days later the patient was sent to a convalescent home. A month afterwards the patient was readmitted as the uterus was still enlarged and tender, the left appendage was enlarged, and there was a free pink vaginal discharge. A few days later, under anaesthesia, the uterus was explored and an attempt to clear the cavity of its contents with a blunt curette had to be abandoned. The abdomen was opened and the uterus, tubes, and ovaries removed. On cutting open the uterus a mass of chorion-epithelioma was seen in the fundus penetrating into the muscular wall, and the left ovary showed a theca-lutein cyst. Microscopic sections of the uterus showed the characteristic appearances of chorion-epithelioma. The points of interest were the behaviour of the uterus on dilating the cervix and the rapidity with which the chorion-epithelioma showed its presence.

Dr. D. DOUGAL referred to a case which had been under his care where chorion-epithelioma developed equally rapidly.

## TUMOURS OF THE CENTRAL NERVOUS SYSTEM.

At a meeting of the Bristol Medico-Chirurgical Society on February 11th, Mr. J. LACE FIRTH in the chair, Mr. PERCY SARGENT read a paper on the surgery of tumours of the central nervous system.

Mr. Sargent laid emphasis first on the necessity for accurate diagnosis and for close co-operation between the neurologist and the surgeon. Tumours of the pituitary region, he said, manifested themselves in two ways. Function was disturbed, with changes in the skeleton and in other glandular functions, hairlessness, etc.; pressure produced intolerable headaches, with falling vision. It was for the latter symptoms that surgical intervention was required. These tumours fell into two divisions. Simple adenomata of the pars anterior excavated the sella, and also pushed up the optic chiasma, but in invading the cranial cavity they remained encapsuled. With these types of tumour glandular disturbances might occur; and such patients bore operations badly. The second division was composed of suprapituitary tumours: (a) meningeal tumours of the interpeduncular space, (b) tumours or cysts of complex structure probably arising from the infundibulum; with these, the glandular changes were not remarked. Either type might be approached (1) by the temporal route, used by Horsley twenty years ago;

(2) from below, through the sphenoidal sinus as advocated by Cushing; (3) by means of a frontal osteoplastic flap, as devised by Frazier. Mr. Sargent preferred the last method. The prognosis was best with adenomata; with the improved technique the proportion of satisfactory results was quite gratifying. Suprapituitary tumours were less satisfactory. Some were cystic and contained cholesterol; with these there seemed to be a risk of death from toxæmia, following the liberation of the fluid. Cerebello-pontine tumours were usually neuro-fibromata of the auditory nerve; others were cholesteatomata, or "pearl tumours." The former were usually firm, solid, encapsulated tumours, but might be soft or even cystic. They enlarged the internal auditory meatus, sometimes to a remarkable degree; this could be demonstrated by skiagraphy. Deafness and tinnitus might be the only symptoms for many years. Loss of function of the vestibular part of the nerve was early demonstrable, and loss of the corneal reflex of the same side was also frequent. Later, the classical signs of tumour—headache, vomiting, papilloedema—appeared. By this time an operation had become a more difficult as well as a more hazardous proceeding. The tumours should not be removed *en masse*; this could be done, but the resulting disturbance to the vascular supply of the medulla commonly induced death. The tumour should be removed intracapsularly, by morcellation. Decompression might be performed if piecemeal removal was not thought advisable, but the results were not nearly so satisfactory. The group of endodermiomas was histological rather than regional, though the tumours were meningeal and tended to be superficial. They cupped but did not infiltrate the brain, and probably arose from the arachnoid tufts which formed the Pacchionian bodies, and so tended to be found about the longitudinal sinus. Growing very slowly, they might attain very large size before giving rise to symptoms. These tumours might often be diagnosed and localized with certainty before signs of general pressure appeared; this was a great advantage, as an osteoplastic flap could be employed. A two-stage operation was not advised; the patient might die between the two operations. These tumours formed only a small proportion of the whole class of tumours of the cerebrum, and were rare in the cerebellum. A glioma of an infiltrating type was the common tumour. For these, decompression and partial removal gave some relief; and it seemed that gliomata were favourable tumours for the action of radium buried in their substance. In any case, where there was a high degree of intracranial pressure any operation was fraught with difficulty and danger; the classical signs of tumour should be regarded rather as danger signals, or even portents of impending death. Early and accurate diagnosis were the points of essential importance. Spinal tumours provided some of the best examples of the benefits derived from operation on the central nervous system. A large proportion were benign extramedullary growths, and in all these there was some stage where operation afforded prospect of complete removal at very small risk. In addition to neurological means of diagnosis and lumbar puncture, skiagraphy after the injection of lipiodol through the occipito-atlantoid ligament afforded a valuable means of localizing the tumour.

### CONGENITAL CYSTIC KIDNEY.

A MEETING of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland was held on January 30th, with the President, Dr. C. M. WEST, in the chair.

THE PRESIDENT showed a case of congenital cystic kidney accompanied by various other abnormalities in a seven months foetus which he had received from the Rotunda Hospital. There was a large cystic kidney on the right and a commencing similar condition on the left side. The ureters were greatly distended and the bladder was much dilated and hypertrophied; this, however, was not due to any obstruction to the outflow of urine, but was apparently of a similar nature to cases of congenital hypertrophic stenosis of the pylorus. The vas deferens of each side opened independently into the lower part of the hypertrophied bladder, and there was no sign of any seminal

vesicles. There was a Meckel's diverticulum; and the left foot was clubbed. Dr. West showed the various abnormalities by means of lantern slides and the actual specimen, and discussed the causation of the conditions found.

Professor A. F. DIXON suggested that in this case the caudal part of the large bladder really represented a much dilated first part of the urethra, and that the reason that the seminal vesicles were not present might be due to the fact that the part of the Wolffian duct from which they normally arise had been taken up and incorporated into the much dilated cavity of the bladder.

### Nutrient Foramina of Bone.

Professor E. J. EVATT read a preliminary note on the nutrient foramina of the longer bones of the extremities. He showed by specimens and drawings of them that as soon as the articular epiphyses were demarcated the bones were practically models of the adult bones. Each of these longer bones began with two nutrient foramina—one above and the other below the middle of the shaft; the upper foramen was directed distally, and the lower towards the proximal end of the bone. The spatial relationships of the foramina to each other and to the ends of the bone were retained throughout life. The final direction of the surviving foramen or foramina was determined by the constant or changing direction of the arteries to the bones, and not by an inequality in the growth of the bones themselves. Many of the bones retained the two foramina throughout life. He believed that the epiphyses did not add to the length of the bones, and that the growth of the bones was in no sense local but general.

Professor A. F. DIXON did not agree with Professor EVATT's conclusion regarding the growth of bone. It was contrary to the results obtained by madder feeding and other experimental work.

A series of casts and photographs, showing the development of the external nose in the orang, the chimpanzee, and the gorilla, was shown by Professor DIXON. The chief peculiarities of the nose in these animals were explained, and the condition in each contrasted with the external nose of man.

At a meeting of the West London Medico-Chirurgical Society, at the West London Hospital on February 6th, Dr. BENJAMIN MYERS reviewed the subject of the nutritional disturbances of infancy, dealing with those nutritional states occurring in infancy in which, so far, no pathological or bacteriological lesions of any primary consequence had been found. To comprehend nutritional disturbances it was necessary to appreciate fully the importance of food. Human milk must be considered the ideal food, containing not only proteins, carbohydrates, fats, salts, and water, but also the ferments and vitamins which must be kept in view. Further, it was necessary to remember the relative percentages of the salts, and the fact that human milk contained more potassium and iron than cow's milk, while the latter showed a large percentage of calcium and phosphates. The great importance of correct feeding with pure milk of definite composition was considered; also the difficulty of fat digestion, the necessity of caution in maintaining the carbohydrate percentage; the danger of too strong whey salts, and of too high percentage of sugar. The importance of breast-feeding was strongly emphasized. The discussion was opened by Dr. HUGH THURSFIELD and Dr. ERIC PITCHFORD.

At a meeting of the Hull Medical Society on February 6th, the President, Dr. T. RITCHIE ROOPER, in the chair, Dr. F. C. EVE read a paper entitled "Diabetic treatment simplified." In this he expressed the view that modern methods involving food value estimated in calories and the blood sugar tests were too complicated to apply in private practice. Hence, in diabetes, it was far better to regulate diet and the use of insulin consistently by urine testing rather than to attempt the impossible by blood testing, which could not be done often enough. The only means whereby the doctor could see at a glance what happened in his absence was for the patient to chart a curve of his sugar excretion every day. Dr. EVE had devised and used a simple fermentation method by means of which any adult could do this satisfactorily. Caloric estimation and blood sugar tests were rarely needed. If the ferric chloride test became positive for ketones, then bread and insulin must be added. Dr. W. W. ADAMSON dissented from the view that the treatment of diabetes could be adequately controlled by the estimation of urinary sugar, which might give a false impression of the percentage of sugar in the blood. Hyperglycaemia might be present without glycosuria.

## Reviews.

### INTERNAL SECRETIONS.

THE third edition of Professor SWALE VINCENT's book on *Internal Secretion and the Ductless Glands*<sup>1</sup> brings the knowledge of these glands up to date and affords the reader a select bibliography, guided by which he can, if he so wish, compile a complete one in any particular branch of the subject which interests him. The book is a valuable corrective to the wilder statements made frequently in some of our contemporaries and the absurd claims of the nostrum-mongers who sell to, and through, the profession every imaginable kind or combination of tissue extracts. There are drug makers just as clever in passing off their wares to medical men by speciously scientific advertisements as are the patent medicine vendors in gulling the public by more blatant advertisement in the daily press.

In the section on the reproductive organs we note that the latest publications of Voronoff and Steinach are critically considered. The first case of Voronoff was a man from whom both testes had been removed for tuberculosis, who resembled a eunuch; was hairless and fat, and had large mammae. A testis was grafted in four pieces. The graft only survived three months and then suppurated. During this period the beard grew and the man had to shave, which he had not done for twenty years. One man of 74, with marked signs of senility, was transformed into a vigorous, energetic person, but in some other cases the results were not so definite. Time and more cases are required to form a true judgement on the value of monkey gland grafts. Steinach's method of tying the vasa deferentia causes increase of the interstitial tissue of the testes and signs of rejuvenation, but it is not yet known how long the beneficial effects last. The wisdom of sterilizing criminals by this means, now legalized in certain States of America, is doubtful if, as is alleged, increased sexual productivity results. It is, the author states, as yet undetermined how far the germ cells of the seminiferous tubules share in the internal secretion which has been attributed to the interstitial tissue. A very interesting account is given of feminizing and masculinizing experiments which have been carried out by castration and grafting. Not only changes in physical form, but in eroticism, are said to result. Hermaphroditism and psychical homosexuality are considered in view of these animal experiments.

In dealing with the thyroid, the author describes certain recent success in abolishing goitre by giving children small doses of iodine. In an ordinary diet iodine is obtained from sea-fish and from milk, eggs, cereals, vegetables, and wine; soil blown upon by sea spray is an important source. It should be pointed out that white flour and bread are robbed by the miller of iodine; along with valuable salts and vitamin B. Prohibitionists should learn that while wine may add essential salts, sweets and white flour pastry rob the diet of these, and also of vitamin B, required for proper digestion and utilization.

Dr. R. PORAK, a professor at the Shanghai School of Medicine, has written a book on the functions of the endocrine glands, entitled *Les Syndromes Endocriniens*,<sup>2</sup> which forms one of a series of French monographs published under the direction of Professor ROGER. Authors of books on endocrinology set about their task in different ways, but for the most part adopt the classification of diseases due to increased or diminished function of the glands of internal secretion. Dr. Porak treats of the subject from rather a different point of view, and readers will be disappointed who expect to find here a neatly arranged table indicating the effect of hypo- or hyperfunction of endocrine glands, and who seek for an exact formula to balance a glandular defect and to cure a patient with certainty. Sufficient evidence has not yet been accumulated to warrant such a

simple classification; many of the generally accepted symptoms of endocrine deficiency require a critical review. In particular, Dr. Porak is not satisfied with evidence usually presented in favour of hyperfunction of internally secreting glands; he insists on a more accurate study of certain nervous syndromes wrongly attributed to derangement of internal secretion. Such are the special characters of the book, wherein are described successively the relations of internal secretions to the development of the body, to sexual functions, to the cardio-vascular system, to diseases of the excretory organs and skin, and to disturbances of nutrition. He gives reasons for his decision to include diabetes within the scope of the book, and has a special chapter on the relation of the pathology of the blood to symptoms and signs of endocrine upset. The functions of the thyroid, parathyroid, and suprarenals are dealt with in sequence. One feature of the book is the frank and open discussion of the fundamental doctrines of this rapidly growing branch of medicine. It will serve a good purpose if it destroys confidence in the blunderbuss preparations advocated by some organotherapy enthusiasts and directs attention to the necessity for more careful thought about the influence which one secretion exerts on the others. It is a useful and stimulating addition to endocrine literature.

### THE PROBLEMS OF TUBERCULOSIS.

Dr. AUBERTIN, in his book on the development of bacillary infection in man,<sup>3</sup> deals only with what the French call "*bacillose*," or infection with the tubercle bacillus of Koch. He discusses in great detail every known aspect of the process by which it gains access to, primarily infects, and becomes latent or active in the human body. The book is not so much a record of the young author's own experiments and observations, as a careful examination and critical analysis of the published work and theories of others. It consists of four parts. In the first an account is given of the views of French observers regarding the development of tuberculous infection in man; in the second these are examined critically; and in the third and fourth an effort is made to demonstrate the factors of the conditions favourable to tuberculous infection. The first two parts of the book will leave the reader in a maze of doubt, for the author's critical examination of the conceptions and observations of the best known writers on tubercle infection brings out a mass of contradictory evidence. While one holds that infection only occurs through the intestinal tract, another will argue that it can only occur through the lungs; and so on with a number of other problems, such as the questions of the age at which primary infection takes place; of acquired immunity; of the freedom or otherwise of native races from tuberculous infection; of the site of original infection as observed clinically, in autopsies or experimentally; of the relation between human and animal tuberculous infection; of secondary infection and the influence of intensity of infection; and other important questions. In the final sections of the book, however, he sums up what he considers may be regarded as more or less established facts; and states that of all the theories at present held regarding the conditions under which tubercle infection attacks mankind, only one is definitely accepted by all—namely, that tubercle is a contagious disease caused principally by expectorated matter containing tubercle bacilli. He arrives at three conclusions regarding liability to infection. The first is that there is no specific immunity, and the theory that tubercle bacilli, which are universally latent in almost everyone, cause immunity spontaneously, has not the importance sometimes ascribed to it. Secondly, that though there is no specific immunity, the various biological defences the human body possesses, notably the leucocytes, vary with the individual. On the other hand, independently of the influence of predisposition, tubercle infection (given equal doses of the bacilli) will develop more readily the nearer the subject approaches the antecedent conditions favourable to infection. These seem foregone conclusions. His third conclusion is that the tubercle bacillus specially selects certain

<sup>1</sup> *Internal Secretion and the Ductless Glands*. By Swale Vincent, M.D., F.R.S., etc. Third edition. London: Edward Arnold. 1924. (Demy 8vo, pp. xv + 453; 110 figures, 25s. net.)

<sup>2</sup> *Les Syndromes Endocriniens*. Par le Dr. R. Porak. Préface du Prof. H. Roger. Bibliothèque des Grands Syndromes. Paris: G. Doin. 1924. (Med. 8vo, pp. vi + 401; 19 figures, 4 plates. Fr. 23.)

<sup>3</sup> *Le Développement de l'Infection Bacillaire chez l'Homme. Le Rôle du Terrain*. Par Dr. E. Aubertin. Préface du Pr. Agrégé Leuret. Paris: Gaston Doin. 1924. (Roy. 8vo, pp. 339. Fr. 20.)

tissues and organs for its development. It does not attack non-vascular tissues and those only slightly vascularized, but has a special affinity for highly vascular organs and tissues, and for young persons in the full activity of their bodily functions. The final pages of the book contain remarks on prophylaxis. Although unhealthy environment, poverty, and vice must be combated, the removal of these conditions will not be efficacious unless at the same time efforts are made to detect persons who are expectorating sputa containing tubercle bacilli. Dr. Aubertin recognizes the practical difficulties in carrying out these measures effectively, and urges the need in France of Government action; he quotes a statement of M. Poincaré in 1924 to the effect that the campaign against tuberculosis will be amongst the most urgent matters occupying the attention of the French Parliament in the future. Dr. Aubertin's book as a whole is an able and full critical exposition of our knowledge of tuberculous infection.

#### A TEXTBOOK OF PHYSIOLOGY.

*Fundamentals of Human Physiology* is a book of moderate size, and its scope is precisely what the title indicates, Professor J. J. R. Macleod and Dr. Pearce having kept to their text with commendable strictness. It is always interesting to see what masters in their subject consider "fundamentals"; and in the book before us we have the Institutes of Medicine—as the old term for physiology was—expounded by two experienced teachers in Canadian medical schools.

We do not wonder that the book is already in its third edition,<sup>4</sup> for the style is so easy that the reader does not at first appreciate how much quite recent physiology is compressed into the volume. The authors begin with short accounts of the physics and chemistry requisite to an understanding of physiology to-day; in fact, we cannot remember previously to have seen the vast subject of the proteins summarized in one and a half pages.

A refreshing sanity pervades the whole treatment of the bodily functions, and much useful information is given, notably in the remarks on hygiene with which the volume closes. We are relieved to find that such eminent physiologists as the authors do not scorn to use the expression "lower the vitality" when discussing the subject of draughts predisposing to "catching cold." They also condescend to criticize the too high seat in the w.c., against which there was a sort of crusade in this country a few years ago. In 99 per cent. of cases it is too high and is level instead of sloping backward to allow the thighs to exert on the abdominal wall the powerful supporting pressure which Nature intended. The way in which the innervation of the circulation and of the respiration is dealt with is interesting, as is indeed all that is said about the nervous system; "psychic reflexes" are not explained away as though the psychic element was not a causal one. We should have welcomed a chapter on posture and animal mechanics, and surely we might have had more than so casual a reference to insulin; is not this carrying modesty too far?

The seventy-one illustrations are well chosen; the coloured diagram of the tubules and blood vessels of the kidney is very valuable for teaching purposes.

#### CATENARY PATHOLOGY.

The expression "catenary" as applied to pathology suggests itself as an appropriate interpretation of what Dr. RICKER, of the Municipal Pathological Laboratory of Magdeburg, intends to postulate by the term "*Relationspathologie*" in his *Pathologie als Naturwissenschaft*,<sup>5</sup> a book which he has written for the edification of pathologists, physiologists, doctors, and biologists. It is an exhaustive exposition of his theory that pathological and physiological processes are one and the same, that they depend on a chain of linked physical action within the body, set going by internal or

external stimulation of the nervous system, and that both physiology and pathology are natural or physical sciences. Dr. Ricker considers that they should be taught as physical sciences without reference to hygiene or medicine. On this foundation the author constructs his theory of catenary pathology. Disease in all its forms commences with a stimulation of the nervous system, which directs by vaso-motor action the circulatory system and blood stream, while it, in its turn, acts on the organs and tissues, influencing metabolism and other functions of the body. There is thus a chain of processes, beginning with the nervous system and ending with the organs and tissues. If the results are healthy or normal, the chain of processes is physiological; if unhealthy or abnormal, pathological. Inflammation, tumours of all kinds, macroscopic and microscopic anatomical changes, are all produced by the initial action of the nervous system on the circulatory system, causing dilatation or constriction of the blood vessels, and so effecting a slowing or arrest of the blood stream, with subsequent massing of leucocytes, exudation and interference with normal metabolism. If these views are accepted by pathologists, Virchow's time-honoured cellular pathology vanishes in the light of *Relationspathologie*, as alchemy in the light of chemistry, and astrology in that of astronomy. In fact, throughout the volume Dr. Ricker writes contentiously, and attacks not only Virchow's theories but many others. He does not accept, for example, the usual explanations of chemotaxis and phagocytosis; and infective (bacterial) pneumonia he does not consider a struggle against bacterial invasion. He seeks to prove in argument and by experiment that the cell has not and cannot have an independent existence. The cellular theory, by which individual cells can be stimulated directly for self-maintenance and multiplication, ignores the relation between the blood stream and the nervous system. All cell and tissue changes stand in causal relation to the blood, the circulation, and the nervous system, and the chain of processes, of which the nervous is the earliest in point of time, is carried in different directions and produces macroscopic and microscopic anatomical changes according to the nature of the cells or tissues concerned. It is too soon to determine how far this view of pathology will be accepted or not; but among his own countrymen Dr. Ricker has many active opponents, one of whom remarks that his description of Virchow's cellular pathology is a caricature (*Zerrbild*).

His work, however, is suggestive in many respects, though it is difficult at times to follow him on account of the involved thought in many of his sentences. He divides his subject into three parts—a physiological, a pathological, and a philosophical criticism—in which the conceptions of life, cells, inflammation, degeneration, tumour formations and so on, and the principles of a catenary physiology and pathology are tested logically. His pathology does not concern itself with mental processes or mental disease. He regards these as belonging to mental and moral sciences or metaphysics. Pathology and physiology, being only concerned with physical processes, have nothing to do with the psychical. Psychology, however, is regarded as a science which links up the physical with the psychical. It commences where the physical leaves off. On the other side are the practical sciences of hygiene and medicine—the one for the maintenance of normal physiological processes, the other for the restoration of the abnormal pathological to the normal. Dr. Ricker would be more convincing if he did not protest so much, repeat his theory so often, or involve his arguments so obscurely at times in long and parenthetical sentences. His book is scarcely one that will be read with ease. It has a good index and a bibliography of sixty-three articles or books written by himself or his collaborators.

#### BASAL METABOLISM.

We recommend the new book by Dr. EUGENE DU BOIS, *Basal Metabolism in Health and Disease*,<sup>6</sup> to the attention of physicians as well as physiologists. For many years the experiments on calorimetry which physiologists conducted

<sup>4</sup> *Fundamentals of Human Physiology*. By R. G. Pearce, B.A., M.D., and J. J. R. Macleod, M.B., D.Sc., F.R.S., assisted in the third edition by Dr. Norman B. Taylor. Third edition. London: H. Kimpton. 1924. (Med. 8vo, pp. 349; 71 figures, 8 coloured plates. 15s. net.)

<sup>5</sup> *Pathologie als Naturwissenschaft*. By Dr. R. Ricker. Berlin: J. Springer. 1924. (Med. 8vo, pp. vii + 391. Paper cover, gold marbled.)

<sup>6</sup> *Basal Metabolism in Health and Disease*. By Eugene F. Du Bois, M.D. Philadelphia and New York: Lea and Febiger. 1924. (Med. 8vo, pp. viii + 372; 78 figures. 4.75 dollars.)

and the new knowledge of the general metabolism of the body which was gained did not reach most medical practitioners, since it was published chiefly in physiological journals. Calorimetry experiments laid the foundation of the science of nutrition, yet, long after calories were understood and talked about, the cumbersome and expensive apparatus by which these were estimated was installed only in the best equipped physiological laboratories, and few people would have predicted that such appliances would soon assume a form which could be carried to the bedside. In recent years it has been shown that estimations of metabolism by indirect calorimetry are of great value in the diagnosis and proper control of such diseases as exophthalmic goitre, diabetes, and the anaemias. Fortunately the ingenuity of physiologists in devising simpler apparatus has kept pace with the increasing usefulness of basal metabolism tests, so that it is easy now for these tests to be carried out by the practising physician without any special training in technicalities. In this adaptation of physiological research to practical medicine Dr. Eugène Du Bois has played a prominent part, and it is fitting that he should have taken up the task in such a book as this of translating the whole subject of basal metabolism out of the realm of pure physiology into the domain of clinical medicine. He has succeeded in explaining the subject very clearly, and has written a book which should be very useful to physicians, advanced medical students, physiologists, and dietitians.

The first part of the book deals with metabolism in health. The earlier chapters describe the nutritional requirements of the body and the general principles of metabolism. Later the author turns to the different forms of respiration apparatus and the methods used in calculation. In the second part of the book, devoted to metabolism in disease, he discusses the value of basal metabolism tests in diabetes, diseases of the thyroid, adrenal, pituitary and sex glands, in diseases of the blood, heart, and kidneys, and in fever. But in this portion of the book, as in the earlier part, he does not confine himself simply to the value of tests for estimating the basal metabolic rate; he covers much more ground than this, surveying the whole physiological exchanges of the body in health and disease.

We believe that this book will prove very useful to those who are looking for a comprehensive and trustworthy account of the subject with which it deals.

#### A CANADIAN LOYALIST.

In the year 1647 two brothers named Ryeerzoon emigrated from Holland to America, and settled in New York, then New Amsterdam. The name eventually became Ryerse and afterwards Ryerson. In his autobiography, *Looking Backward*,<sup>1</sup> Major-General G. S. RYERSON of the Canadian Medical Service tells us how he is the direct descendant of one of the two brothers, and how his grandfather, with others of the family, remained loyal to the British during the American Revolution, and, after having their property confiscated, emigrated into what was then the wilds of Canada. His grandfather became a loyalist soldier at a very early age, and performed gallant service during the Revolution. His father, who was born in 1791, and was one of six brothers, also became a soldier, and fought and was severely wounded in the campaign of 1812-14 against the United States. Eventually he and four of the brothers took to the ministry, one, the Rev. Dr. Egerton Ryerson, attaining eminence in the Methodist Church. These details of his ancestry are related in the early chapters of the autobiography, and are followed by chapters of General Ryerson's own early life, education in Edinburgh, Paris, and Vienna, and his professional career as professor of eye, ear, and throat diseases in the Trinity Medical College and University of Toronto. At the time of the Fenian raid of 1870 he held a temporary commission as ensign in a regiment of foot, but saw no active service. He took part, however, as a regimental medical officer in the campaign of

1885 against Louis Riel and the Indian rebels of the Northwest. At that time he had organized a bearer section, and he gives a graphic and interesting account of his journey with it to the area of operations and his subsequent experience, during the fighting at Fish Creek and Batoche. A chapter is devoted to his venture in politics, when he stood three times as a Conservative candidate for a Toronto constituency and was elected a member of the Legislature on two of these occasions. The remainder of the book is taken up with the author's activities in the Canadian Militia Medical Service, the Canadian branches of the St. John Ambulance Association and British Red Cross Society, with his work as Canadian Red Cross Commissioner during the South African war, and with accounts of visits paid to England, Spain, Budapest, Japan, and Hong-Kong, and to France during the great war. Everyone will sympathize with him in the tragic family bereavements from which he suffered in 1915. There are several inaccuracies throughout the book as to names, places, and dates, some probably due to inadequate proof-reading. The Geneva Convention, for example, is dated 1865, and the International Conference of Red Cross Societies is said to have been held in London in 1912; in that year it was held in Washington. It is also disconcerting to find a medical writer to-day referring to anti-enteric vaccine as a serum, to a bottled aerated water as containing a considerable percentage of radium emanation, and to the eating of raw fish as a cause of beri-beri. But, notwithstanding these defects, the autobiography will be appreciated on account of the picture it presents of the author's patriotism, loyalty, and faith in the British Empire.

#### NOTES ON BOOKS.

THE new number of *Brain* (vol. XLIV, Part 4) contains an article by Dr. E. D. ADRIAN, F.R.S., of Cambridge, on inhibition, a clinical and pathological study by Dr. James Collier and Dr. J. G. Greenfield of London on the encephalitis periaxialis of Schilder, and another article on encephalitis periaxialis diffusa by Professor Bonman of Amsterdam. The issue also contains notices of recent publications and an index to the volume. The periodical is published in London by Macmillan and Co., and in New York by the Macmillan Company. The yearly subscription in this country is 24s., to be sent to Messrs. Macmillan, St. Martin's Street, London, W.C.2.

Dr. ARTHUR SHEARD'S little book on *Pernicious Anaemia and Aplastic Anaemia*<sup>2</sup> is a thesis submitted by him to the University of Leeds in December, 1923, for which he was awarded the degree of M.D. with distinction. It is a review of fifteen cases of pernicious anaemia which were carefully studied, together with a case of haemolytic jaundice simulating pernicious anaemia in certain respects, and one of aplastic anaemia. Of these patients four died in the Leeds General Infirmary and post-mortem examinations were made. The remainder were kept under observation as long as possible and after discharge from hospital often visited in their homes. The study of this relatively small number of cases has been supplemented by a review of all the cases of pernicious anaemia admitted to the Leeds General Infirmary during the past ten years, particular attention being paid to age and sex incidence, family history, and occupation. The book is divided into two sections, the first of which deals with pernicious anaemia and the second with aplastic anaemia. It is a careful piece of work, and, though it has not opened up any new outlook on the pathology or treatment of these puzzling diseases, the detailed information it contains will be of interest to all who are making a special study of blood diseases.

The 1925 edition of *The South American Handbook*<sup>3</sup> contains a considerable amount of information about the countries and resorts of Latin America, including South and Central America, Mexico, and Cuba. Local descriptions of the districts and towns are combined with the details of railway routes and a guide to hotels. Besides being of service to travellers, the book should be of use to investors and others interested in South America.

<sup>1</sup> *Looking Backward*. By George Sterling Ryerson, M.D., C.M., F.R.C.P. and S. Edin., F.A.C.S., F.S.A. (London), Major-General, R.M.O. Canadian Army Medical Service. Toronto: The Ryerson Press. 1924. (Extra post 8vo., pp. 261; 11 plates. 2.50 dollars.)

<sup>2</sup> *A Contribution to the Study of Pernicious Anaemia and Aplastic Anaemia*. By Arthur Sheard, M.D. Bristol: J. Wright and Sons, Ltd.: London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd. 1924. (Roy. 8vo., pp. vii + 94; 2 plates. 7s. net.)

<sup>3</sup> *The South American Handbook*. 1925. London: South American Publications, Ltd. 1925. (4½ x 7½, pp. lxvii + 628. 7s. 6d. net.)

## Nova et Vetera.

### ALIBERT.

ALIBERT is generally esteemed to be the founder of the French school of dermatology which has had so great an influence on the study of that department of medicine. It was under him that the ancient Hôpital St. Louis became essentially a hospital for diseases of the skin, and from his studies and teaching there sprang the long line of French clinicians and teachers who have always been foremost in every progressive movement associated with their specialty. It is hardly too much to say that the Hôpital St. Louis is the Mecca of the dermatological world; and physicians who make cutaneous diseases their peculiar study scarcely regard their education complete without a pilgrimage thither. It is therefore quite appropriate that Dr. Brodier, who is the curator of the hospital museum and no doubt enjoys special facilities for the purpose, should devote some of his energies to writing the biography of the first master.<sup>1</sup>

Jean Louis Marc Alibert was born on May 2nd, 1768, at Villefranche-de-Rouergue, where his parents occupied a position of some importance. He was originally intended for the Church, and served his novitiate in an order, the Pères de la Doctrine Chrétienne, who conducted an important school in his native town. In 1793, however, owing to the revolution, the fathers suffered dispersal and Alibert proceeded to Paris, where, after certain vicissitudes, he took up the study of medicine, and was received M.D. at the end of 1799. It may be confessed that his subsequent career shows little or no trace of early clerical training.

Alibert's life work began when he was appointed to the St. Louis Hospital in 1802. He found on his arrival at that institution an extraordinary collection of patients suffering from every kind of disease—a collection which only boasted a single feature in common, the fact that they were considered unsuitable for the wards of the Hôtel-Dieu, the institution from which they had been passed on. A very considerable number of these patients were the subjects of some cutaneous malady, and no doubt it was this circumstance which directed the young physician's attention to the study of diseases of the skin. With the wealth of material at his disposal it is not surprising that he was the first to describe several of the more striking forms of cutaneous disease—for example, mycosis fungoides and scarlatiniform erythema. He invented an almost entirely new nomenclature for dermatology, most of which has been quite forgotten, but the terms syphilide, dermatosis, keloid, dermatolysis, which are still in common use, owe their genesis to his ingenuity. Alibert was at his best in his clinical demonstrations, which he conducted, whenever weather permitted, in the open air under a tree, which is

still exhibited with pride to visitors to the hospital. The professor stood on a low platform, while close to it were seated the patients decorated with labels bearing the name of their complaints, which he proposed to illustrate. The pupils occupied benches around.

Alibert was by no means a dry-as-dust lecturer; he illustrated his discourse with quotation, epigram, and metaphor and his classes attracted men from every part of France and from every country in Europe. Such was his reputation as an orator that he was in great demand to pronounce those funeral orations which are one of the forms of tribulation that the French are in the habit of paying to the memory of departed merit. That which he gave on Spallanzani, writes Dr. Brodier, placed him in the front rank of contemporary orators.

In those days the first impression produced on any thinking physician confronted with a mass of patients, all the subjects of cutaneous affections, must have been one of intense bewilderment at the chaotic state of affairs before him. He had no guide to the relationships of the various eruptions presented to his gaze, and his confusion was necessarily heightened by the notorious multifariousness of many dermatoses. In these circumstances the most pressing desire of dermatologists was for some sort of classification whereby this amorphous mob of pathological conditions could be reduced to order. Alibert felt this need to the full, and, influenced by the success which had attended quite recently the classification of the animal and vegetable kingdoms into orders, genera, and species, attempted to do the same for diseases of the skin. He produced an elaborate classification on botanical lines which he depicted graphically in the form of a tree, "*l'arbre des dermatoses*." This was famous in its day, but it was soon found that the divisions to which he assigned various skin conditions were unnatural and unsatisfactory, and it was not long before the scheme was abandoned for the less ambitious but more rational classification of Willan, based on the primary lesions of the

diseases investigated. Indeed, Biett, Alibert's most famous, and long his favourite, pupil, was the chief agent in introducing Willan's work into France, and his advocacy of the British school caused a serious estrangement between them.

Alibert was a prolific writer, not only on dermatology, but also on therapeutics and general literary subjects; his most important work was the *Monographie des Dermatoses*, which was lavishly illustrated by the best artists he could find. It was the first illustrated book on diseases of the skin to be published in France.

Alibert continued to live in Paris till his death. He had many friends in the literary as well as the scientific world, and was very hospitable. He died on November 4th, 1837, and his funeral oration was pronounced by Cruveilhier.

The picture Dr. Brodier has drawn of Alibert as a man and a clinician in the eight chapters of his book is that of a generous, warm-hearted, eloquent son of France, a keen physician, proud of his profession, in which he takes high, if not the highest, rank, as the founder of the French school of dermatology.

ALIBERT.

## ACUTE FOOD POISONING.

BACTERIAL food poisoning in this country is almost invariably due to infection of food with bacteria of the salmonella group, such as set up acute gastro-intestinal irritation revealed by vomiting and severe diarrhoea. The more serious form of food poisoning, botulism, is of an altogether different character and is fortunately extremely rare in these islands. The group of microbes now spoken of as the salmonellas may be more familiar to some readers by another name, such as the Gaertner group or the paratyphoid-enteritidis bacteria. The name "Gaertner group" was satisfactory whilst we thought that the *Bacillus enteritidis* of Gaertner was the commonest or most important member of the family; but when later it became apparent that this title was inadequate and misleading the food poisoning bacteria were more frequently referred to as the paratyphoid-enteritidis group—a cumbersome denomination from which we have been delivered by a further advance of knowledge which separated the paratyphoid bacteria proper from the common agents of food poisoning. The hitherto less popular name "salmonella" has been kept alive by some bacteriologists from the beginning, and now seems the most suitable appellation, in spite of the fact that it may erroneously suggest some connexion with salmon, and so give the impression that this fish is particularly associated with food poisoning. The name salmonella has fewer drawbacks than any, and possesses historical justification, being the first name these microbes received. It was, we believe, originally proposed by Lignières, after Dr. Salmon, who isolated the bacillus of hog cholera.

The salmonella bacteria have always been a troublesome genus to the bacteriologist. Alike in morphology, and almost alike by common culture tests, the members of this group can only be distinguished from each other by agglutination reactions. Serological tests easily separate Gaertner's bacillus from the paratyphoid group, but great skill and patience are needed to distinguish the individual paratyphoid bacilli A, B, and C from *B. aertrycke* and *B. suiptifer*. The ultimate court of appeal, the agglutination absorption test, has discriminated a steadily increasing number of new types of paratyphoid bacilli, given different names by different workers, thereby adding to the confusion.

We welcome the Medical Research Council Special Report No. 91, entitled "An Investigation of the Salmonella Group, with Special Reference to Food Poisoning," chiefly because it contains important information about the distribution of the food poisoning bacteria and the way in which they act, but we are glad also that it gives an authoritative lead in terminology. This is found in the first part, which records the serological studies Mr. Bruce White has carried out on the classification and behaviour of bacilli of the salmonella group. We do not propose to enter into the details of these experiments, though they are of much technical interest, but observe in passing that Mr. White's conclusions support Dr. Schütze's classification, even if they call for some eliminations and

the addition of at least one new type. He distinguishes *B. enteritidis*, *B. paratyphosus* A, *B. paratyphosus* B, *B. aertrycke* (four types), *B. suiptifer* (including *B. paratyphosus* C and the hog cholera type), and *B. abortus equi*.

In the second part of the report Dr. Savage and Mr. White arrive at some very important conclusions about the distribution and disease-producing powers of the different members of the salmonella genus. *B. aertrycke* is the commonest agent of food poisoning in man; it causes enteritis in mice, guinea-pigs, rats, birds, and calves. The paratyphoid B bacillus does not cause food poisoning; it possesses no irritating toxin; though responsible for paratyphoid fever in man, animals are not susceptible to this infection. Gaertner's bacillus causes food poisoning in man and illness in animals, notably cows and rats. *B. suiptifer* has a low virulence for man, and can cause food poisoning only in exceptional circumstances; occasionally it is a primary cause of disease in pigs, but usually only a secondary invader of pigs suffering from hog cholera. These views contradict many oft-repeated statements about the paratyphoid B bacillus and the suiptifer bacillus, but they bring a welcome order into this ill assorted group. The scheme which the Ministry of Health promoted early in 1921 for the investigation of outbreaks of food poisoning has given Dr. Savage unique opportunities for the study of the salmonella bacteria, but we need not accept his views out of deference to his experience alone; for in the third section of the report we come across some experiments which will be impressive to the unconvinced.

Outbreaks of acute gastro-enteritis due to canned foods are usually characterized by rapid onset and rapid recovery; no pathogenic bacteria can be isolated from the sufferers or from the food, and the blood serum does not as a rule show agglutinins for the salmonella bacteria. Feeding experiments by giving the peccant food to animals yield negative results, but by inoculating animals with the food it is sometimes possible to work up low titre antiserum for salmonella bacilli. The essential feature, therefore, appears to be the existence of a toxic substance having a local irritant action, and to investigate this Dr. Savage and Mr. White adopted the plan of feeding young rabbits with large doses of salmonella bacilli and killing them after six to eight hours, to observe the appearance of the stomach and intestine. In this short interval no symptoms appeared: there was no diarrhoea and no vomiting. When *B. aertrycke* or Gaertner's bacillus was given by the mouth to animals, using either living germs, or cultures killed at 60° C., or cultures boiled for ten to thirty minutes, a well marked irritant action on the stomach and duodenum was noticed; in some cases the stomach was violently inflamed, much swollen, and showed many petechial haemorrhages. Dr. Savage and Mr. White obtained a strong impression, which, however, could not be definitely confirmed, that the heating of suspensions of the aertrycke bacillus and Gaertner's bacillus tended to accelerate the irritant action on the alimentary tract. No such irritant action was noticed after feeding animals with cultures of the paratyphoid B bacillus.

Both Mr. White and Dr. Savage thought to confirm these results by experiments on themselves. Mr. Bruce White observed sensations of tingling and a rash with injection of hair follicles when cotton-wool pads soaked in emulsions of aertrycke bacillus were strapped on his arm, but no definite reaction with the paratyphoid B bacillus. Dr. Savage consumed an emulsion of an agar slope of the paratyphoid B bacillus

heated at 66° C. for thirty minutes, and another heated at 100° C. for twenty minutes, and noticed no irritant action on the alimentary tract. From these experiments they conclude that heat-killed salmonella bacteria, particularly those responsible for food poisoning, exert a marked irritant effect on the intestines; this irritant action is slight or absent with paratyphoid bacilli B and C. The irritant action is local and independent of the immunity of the animal to invasion by the living microbes.

These and other experiments recorded in this report must lead to a revision of views about some of the food-poisoning bacteria. It seems that the paratyphoid B bacillus ought not to be included in this group. Under natural conditions it only attacks man and causes paratyphoid fever only. It differs from the true food-poisoning bacteria in not possessing the same irritant effect on the bowel, and in the fact that it readily penetrates the intestinal barrier and can be found in the blood. The longer incubation period and gradual onset of paratyphoid fever afford clinical evidence against local irritant action. Outbreaks of food poisoning alleged to be due to paratyphoid B were in reality caused by some other microbe. *B. aertrycke* and Gaertner's bacillus have a wide range of natural hosts, including man, mice, rats, and most domestic animals. They differ from the paratyphoid B bacillus in possessing marked irritant action on the bowel and in not invading the tissues of the body in man, though they are markedly invasive for other animals; the low agglutination titre of the blood of patients suffering from infections caused by *B. aertrycke* and Gaertner's bacillus is explained by the lack of general invasion. The toxin which these bacteria form when living in food is not destroyed by boiling. For *B. suipestifer* the pig is the natural host, and it still remains to be decided whether it and the paratyphoid C bacillus are separate organisms. Probably the suipestifer bacillus is frequently ingested by man, but only one outbreak of food poisoning in England has been definitely traced to it; in this outbreak, investigated by Dr. Savage, cheese was the offending article.

To sum up, probably three-quarters of the outbreaks of food poisoning in England are due to the aertrycke bacillus, and the low death rate (about 1 per cent.) may be explained by the low invasive power of this bacillus. Next in importance is Gaertner's bacillus, which causes a more serious infection as a rule. Other salmonella bacteria play a very small part, if any, in acute food poisoning.

### CHEST SURGERY.

Chest surgery seems to be only just in the making. Although MacEwen was the first surgeon to demonstrate that thoracotomy could be safely performed without special pressure chambers, British surgeons did not follow his lead, and British surgery has, on the whole, left the thorax somewhat neglected. Perhaps one reason for this is that in chest surgery there must be close co-operation between physician and surgeon, so that diagnosis and operative technique may advance together. It is the same in brain surgery: the physician must diagnose and localize correctly; but he must do more, he must inform himself of every advance the surgeon makes, so that they may together judge of further possibilities. Even though the surgeon be a most skilled diagnostician, cases requiring intrathoracic surgery will not come to him until they have passed through the hands of the general practitioner (and perhaps the consulting phy-

sician too). Most of the present generation of practitioners can recall the time when cases of appendicitis did not find their way as a matter of course to the surgeon. There is to-day no great eagerness to seek a surgical opinion on purely thoracic cases; yet without this there can be no advance.

Professor G. E. Gask's address to the Southampton Division of the British Medical Association on the possibilities of exploratory thoracotomy, with which this issue opens, comes as a timely reminder that, in the words of Pierre Duval, "surgery of the lung takes its place amongst the recognized procedures of general surgery."<sup>1</sup> Professor Gask refers briefly to the evolution of thoracic surgery during the war—an evolution to which he himself was no small contributor, with the assistance of his physician colleague Dr. K. D. Wilkinson. At first the honours lay with the French surgeons, notably Duval, but at the end of the war the surgeons of the British army were no less bold and no less successful. The great progress made during the war in the surgery of gunshot wounds of the chest, and the advantages derived from collaboration between surgeon and physician, were clearly indicated in the paper by Mr. A. L. Lockwood and Professor J. A. Nixon which appeared in the BRITISH MEDICAL JOURNAL early in 1918.<sup>2</sup>

The problem Professor Gask sets out to consider is the extent to which the lessons of war surgery may be applied to intrathoracic surgery in civilian practice. Everyone knows now that a wide opening of the thorax is not followed by complete and dangerous collapse of the lung. After thoracotomy the chest can be closed completely and the wound will heal by first intention. These two facts alone constitute landmarks of supreme importance. Professor Gask advocates that, in cases where there is evidence of pus within the chest which cannot be localized by ordinary clinical methods of examination, a deliberate exploratory thoracotomy is as sound a surgical procedure as exploratory laparotomy in like circumstances. It seems clear that this must become the rule in the very near future. Tumours of the chest offer another field for operative surgery, even though, as Professor Gask says, they are more often than not malignant. It must be remembered, however, that the possibility of malignancy does not prevent exploratory laparotomies, and removal in such cases is sometimes successful even when the growth is malignant.

Of pulmonary tuberculosis and bronchiectasis Professor Gask speaks with more hesitation, and he gives the impression that he is almost content to rest satisfied with the old and well tried method of incision and drainage for empyema. But the failures that occasionally follow this method of treating empyema are too many and too distressing for us not to hope for something better. It is a method that seems to take too little into account the ultimate restoration of function in the affected lung. At present we appear to be satisfied with mere saving of life, and to be almost unconcerned about the patient's subsequent health. The chronic discharging sinus following empyema is a reproach to modern surgery, and Estlander's operation is nothing else than the setting of the seal on hopeless failure.

The medical profession is sometimes slow to realize that new methods of treatment have passed beyond the experimental stage and are well established as safe and sane procedures. Chest surgery is now in that position.

## A MEMORIAL TO SIR JAMES MACKENZIE.

THE Institute for Clinical Research at St. Andrews was established by Sir James Mackenzie five years ago, and readers are aware, through the series of papers communicated by him to this JOURNAL, of the great amount of work of fundamental clinical importance already accomplished there. Through Mackenzie's own efforts and his extraordinary generosity in providing money, the building, together with well equipped chemical and bacteriological laboratories, is the property of the council, and he himself and his personal friends, assisted by grants from the Carnegie Trustees and the Medical Research Council, have met current expenses. It was his ardent hope that the work he began there would be permanent, and no effort is being spared by the council and staff of the institute to give effect to the aims he had in view. An appeal is now being made for contributions to meet the cost of maintenance. It is true to say that of all he accomplished nothing lay nearer his heart than the welfare of this institute, and there could be no more fitting tribute to his life and work than the placing of the institute on a sound financial basis. It has been ascertained that a sum of about £60,000 will be required to produce the minimum income necessary for the scheme, and of this amount £7,000 has already been collected. In future the institute will be known as "The James Mackenzie Institute for Clinical Research, St. Andrews." Donations towards securing its establishment as a permanent memorial to its distinguished founder will be gratefully received and acknowledged by the Honorary Treasurer of the Institute, Commercial Bank, St. Andrews.

## PRESERVATIVES IN FOOD.

DRAFT regulations have been prepared by the Ministry of Health and the Scottish Board of Health to give effect to the principal recommendations of the recent Departmental Committee on the use of preservatives and colouring matter in food. The regulations propose to prohibit the use of preservatives in food with the exception of sulphur dioxide and benzoic acid. The use of a specified proportion of sulphur dioxide would be permitted in sausages, jam, fruit and fruit pulp, dried fruit, beer and cider, alcoholic wines, non-alcoholic wines and cordials, fruit juices sweetened and unsweetened; the use of benzoic acid would be permitted in coffee extract, non-alcoholic wines and cordials, fruit juices sweetened or unsweetened, sweetened mineral waters, and brewed ginger beer. No article of food, however, would be allowed to contain both sulphur dioxide and benzoic acid. The regulations would prohibit the use in food of certain metallic colouring matters, one vegetable colouring matter, and some coal-tar colours. Where sausages, jam, and coffee extract contain preservative the fact is to be stated on a label, and labelling would also be required in the case of articles sold as preservatives of food. The regulations would apply to imported articles as well as to articles produced in this country, but not to articles intended for export or re-export. Copies of the regulations can be obtained from H.M. Stationery Office, Adastral House, Kingsway, London, W.C.2, or 120, George Street, Edinburgh.

## CONGRESS ON SEASIDE TREATMENT OF RICKETS.

THALASSOTHERAPY is defined as embracing all methods of treatment in which sea air, sea water, and seaside sunshine take a share; the French Association of Thalassotherapy, founded thirty years ago by Professor Vernheil of Paris, has, by a natural process of development, added heliotherapy in general, and this, if widely interpreted, might take the association sometimes to the mountains. Sea air might also be held to include sea voyages, and, as our French correspondent told us last week, the profession in

France is beginning to experiment. This, however, only by the way, since for this spring an International Congress of Thalassotherapy is to be held at Arcachon. The long coastline of France is dotted with seaside places from the Belgian frontier to Hendaye, almost within earshot of Fontarabian echoes. It can boast also many places on its Mediterranean seaboard where sun, if not fresh sea air, can often be enjoyed even in winter. Arcachon is a sandy place backed by far-stretching pinewoods on a land-locked inlet of the Bay of Biscay, and ought to be very agreeable at the end of April, when the congress is to assemble for the discussion of the seaside treatment of rickets. The subject will be introduced by representatives of Great Britain (Dr. Leonard Hill and Dr. Webster), France (Dr. Armand Delille), Italy, Belgium, and other countries. A speaker may use his mother tongue, and papers on subjects other than rickets may be contributed, but the committee does not undertake to publish them save in abstract. The congress proper lasts three days (April 27th to 29th), and on May Day the members are to start on a motor trip to Biarritz, about one hundred miles away, and then to St. Jean de Luz and Hendaye, where the French Antituberculosis Society, whose headquarters are in Paris, has one of its sanatoriums for children. The third article of the regulations is that "these congresses are essentially scientific," but it will have been gathered that the committee in Paris knows how to mingle pleasure with business. It has taken steps also, with the co-operation of the hotel keepers and motor proprietors, to protect the pockets of those attending, and the Southern Railway Company will issue first-class tickets to Arcachon and back for £10 2s. 3d. (second class, £7 3s.). At a meeting held at Sir StClair Thomson's house last week a British Committee was formed with him as president and Dr. Campbell McClure (65, Wimpole Street, W.1) as honorary secretary, but subscriptions should be sent to the treasurer, Dr. Robert Pierret (7 bis, rue Raynouard, Paris 16). The president of the congress is Dr. Gilbert, professor of clinical medicine in Paris.

## THE FIRST BOOK IN ENGLISH ON DENTISTRY.

IN 1686 Charles Allen, about whom the *Dictionary of National Biography* is silent, brought out in Dublin a book of fifty-eight pages, *The Operator for the Teeth, showing how to Preserve the Teeth and Gums from all Accidents as also the Description and Use of the Polican*; the only known copy is in the library of Trinity College, Dublin. In the following year, 1687, there appeared a second edition or reprint with an altered title, *Curious Observations in that difficult part of Chirurgery relating to the Teeth, shewing How to Preserve the Teeth and Gums from all Accidents they are subject to*; seven copies are known to be extant, and from that in the British Museum (782, 1.5 (1)) a reprint has been made. Allen considered that he was the first to write on the subject, and Miss Lilian Lindsay, who contributes an introduction, remarks that Berdmore, nearly a century later, made a similar statement, and that the value of Allen's book is not so much its priority or its contents as that it is one of the rare examples of Dublin printing in the seventeenth century—probably one of the most disastrous that even distressed Ireland has ever experienced—when the hearts of writers and printers alike failed them for fear to publish. The surviving part of his teaching is the importance to be attached to the care of the teeth in early life, which is "conducive to the preservation of life and health of children . . . and to the preventing of all those infirmities wherewith they are afflicted." It is dedicated "To the most Honourable and Truly Learned The Physitians, Chirurgeins, and Apothecaries of the City

*Curious Observations on the Teeth.* By Charles Allen. The first known book on dentistry in the English language, 1687. With a short introduction by L. Lindsay. Dental reprints No. 1. London: John Bale, Sons, and Danielsson, Ltd. 1924. (Fcap. 8vo, pp. viii + 25; 1 plate. 5s. net.)

of Dublin," and on the next page, under the original title "The Operator for the Teeth," has a poem beginning with the laudable and disarming sentiment, "Knowing that it is the duty of every man, and especially of such as live under a Civil Government, (where the general Interest always includes the particular) to contribute as much as he can (in his own station) to the publick Good." The work contains seven sections, dealing with: the Nature of the teeth; the alterations of the teeth, with their remedies; the corruption of the teeth, with their remedies, whereto is annexed the description and use of the polican; the restoration of the teeth; the tooth-ake, looseness of the teeth, and decay of the gums, with their remedies; children's teeth; and the "acceleration of the teeth," which gives instructions how to hasten the growth of children's second teeth and also "those in men that are called the teeth of wisdom."

#### GUY'S HOSPITAL BICENTENARY.

A SPECIAL number of the *Guy's Hospital Gazette* has been published to commemorate the bicentenary of the hospital and the centenary of the medical school. Sir William Hale-White, consulting physician to the hospital, contributes a most valuable history of the institution, which is illustrated by interesting prints of the building at different periods. Mr. H. L. Eason, medical superintendent and ophthalmic surgeon to the hospital, supplies details of its present size, constitution, and general activities, and so affords a basis of comparison with the position in 1725. A history of the medical school is contributed by the dean, Professor T. B. Johnston; and the story of dental surgery at Guy's is related by Mr. F. J. Pearce, who points out that though the dental school was only inaugurated in 1889, yet the first dental surgeon, Joseph Fox, was appointed in 1799, and the hospital was probably the first to institute courses of lectures on dental surgery. The history of the *Guy's Hospital Gazette* is sketched by the editor, Mr. L. G. Housden, who describes its progress since a second-year student, T. Cattell-Jones, brought out the first number on October 1st, 1872. Miss F. A. Sheldon, who was lady superintendent of Guy's Hospital Trained Nurses' Institution from 1913 to 1922, writes an interesting account of nurses and the development of nursing at Guy's Hospital during the last two hundred years. Many quaint details, and some even quainter photographs, of the nurses of early times are furnished. Miss Sheldon contributes also a short account of the Guy's Hospital Trained Nurses' Institution, maternity charity, and midwifery training schools. The various students' clubs (in particular the Rugby Football Club) are dealt with, and the volume also includes a description of Guy's Hospital Ladies' Association by Mrs. Lauriston Shaw. The very high standard of the printed matter and the illustrations in this bicentenary number will undoubtedly secure for it the popularity it deserves, especially as the price is only 2s. 6d. a copy. It may be obtained from the *Gazette* Office, Guy's Hospital, S.E.1.

#### CENTRAL AMERICAN DISEASES.

DR. ALDO CASTELLANI visited Central America in the course of last year, and has now published in the *Journal of Tropical Medicine and Hygiene* for January 1st an account of some observations of diseases of Central America. He describes at length the pathology of "Guatemala nodules," a form of filariasis occurring on the Pacific slopes of that country. He is inclined to believe that further investigation will show that this condition is also present in other Central American countries. He takes the view that it is not identical with African volvulus, though very similar to it. Two types of Central American myiasis are distin-

guished according to whether the fly larva is the true cause of the condition or only a secondary invader. A short account is given of rhino-scleroma, a disease generally associated with Eastern Europe, particularly Austria, Poland, and Russia. It is extremely rare in the tropics, with the exception of Guatemala, where Dr. Castellani saw six cases, in three of which ulcerative processes were present, though apparently secondary. With reference to alastrim, in Jamaica, he takes the view that this disease and small-pox are due to two slightly different viruses. Although the two eruptions can hardly be distinguished, yet the general condition of the patient in alastrim is remarkably good, and secondary fever is generally absent. Furthermore, the scarring and pitting in convalescents from alastrim was much less marked than in the case of small-pox.

#### INFLUENZA.

LAST week the number of deaths from influenza in the great towns of England and Wales again increased, from 202 to 291, a considerably greater increase than in the previous week, when only 7 more deaths were recorded than in the week before. The chief reason is that London and the South are now involved; the deaths in London increased from 48 to 76. Two cities other than London—Manchester (23), Leeds (12)—recorded more than 10 deaths; Rochdale and Norwich had 9 each, Bolton and Salford 8 each. The indications are that the deaths will continue to increase in numbers for some weeks more, but there is still no suggestion that the scale of the mortality will be greater than, or even as great as, that of 1923-24. The country has heard with great regret that the King is one of the latest victims of the epidemic, and that his attack is complicated by bronchitis. Fortunately it does not seem to be of great severity, and as it has been taken in good time there is every reason to expect that His Majesty will quickly be restored to health.

#### "THE CRIPPLES' JOURNAL."

WE have received the third quarterly issue of the *Cripples' Journal*. It is published by the Shropshire Orthopaedic Hospital at Oswestry, and aims at making known and helping to relieve the surgical needs of all the crippled persons in this country. Indeed, it may in some sort be considered as the organ of the Central Committee for the Cure and Care of Cripples. At the same time it provides its non-medical readers with a good deal of information on orthopaedic matters. This number contains some valuable contributions. Professor Patrik Haglund of Stockholm gives an account of the care of cripples in Sweden, and describes the three recognized State-aided institutions at Stockholm, Gothenburg, and Helsingborg, and of the measures taken for training the patients in handicrafts and trades. A scheme for the extension of Government aid, formulated by a Royal Commission over which Professor Haglund presided, is at present under consideration. There is a report by the Rev. Ratcliffe Barnett and Mr. W. A. Cochrane of Edinburgh Royal Infirmary on "The cripple [why not crippled?] child in Scotland: what is and what might be." Mr. Cochrane freely confesses that it was only during his service in the orthopaedic department of a large hospital in war time that he "learned the first meaning of the word orthopaedic." If this was the case with a surgeon of Mr. Cochrane's standing it is not wonderful that the profession in general and the lay public should for so long have remained unaware of their ignorance. It is to be hoped that Mr. Cochrane is not alone in receiving enlightenment, and that the lessons of 1914-18 will not be forgotten. The case of Northern Ireland is well stated by Mr. Archibald Irwin of Belfast. Mr. Roeyn Jones begins a scholarly and comprehensive

historical review of orthopædic surgery from the time of Hippocrates. Dr. Maurice Nicoll writes on "Psychological reaction to deformity." Our own observations do not enable us to corroborate Dr. Nicoll's view of the seriousness and frequency of the feeling of inferiority in cripples. In very many cases the physical disability seems to be compensated to some extent by the gift of an unusual amount of high courage and even self-esteem. The other articles in this number are well worthy of the standard set up by its foregoers.

#### IDENTIFICATION OF CANCEROUS TUMOURS.

THE Association Française pour l'Étude du Cancer has undertaken to issue a series of plates to serve as standards for the classification of cancerous growths, and has appointed an influential committee to carry out this somewhat difficult task. The plates will be gathered into an atlas, which, when complete, will constitute an illustrated catalogue of the diverse species and varieties of cancer of every organ of the body, and thus serve as a work of reference on occasions when the nomenclature of tumours is a source of ambiguity, as is not infrequently the case. The nomenclature of tumours is not fixed; different terms are employed to denote the same tumour, and at times the same term is used for different tumours, so that in reading works that are not provided with good illustrations it is not always easy to recognize exactly what growth is under discussion. A more serious disadvantage of a defective nomenclature results from the circumstance that there exists a relation between the morphology of a tumour and its evolution—that is, its tendency to local extension, to generalization, and to glandular invasion. Statistics bearing on these matters have often proved false through failure to discriminate clearly between the varieties of growth to which an organ is subject. The aim of the association, however, is not to impose a new nomenclature, for, however sound the principles of classification adopted might be, the tendency to adhere to accustomed terms would stand in the way of its general acceptance. The difficulty involved in the use of names can be avoided by substituting for them figures of the growths themselves, thus making use of a language at once objective and universal, since it is independent of verbal symbols. The plates will be exact reproductions of the preparations, chosen from a great number of specimens as being representative of the conditions illustrated. It will suffice, it is hoped, in the future, whatever name may be given to a tumour, to indicate the plate of the atlas to which it corresponds, and all ambiguity as to the particular type of growth referred to will be avoided. The atlas is being issued in parts, and the fasciculus before us, which is edited by Bazy and Peyron, contains five plates comprising fifteen figures, illustrating carcinoma and chorion-epithelioma of the Fallopian tube, and chordoma. There can be little doubt that the diagnosis of sections of these tumours could be made by referring to the plates by way of comparison, even by those who could not claim to have expert knowledge of the subject. The aim of the French association may be said to have been fulfilled in these instances, and, provided that a similar standard is maintained throughout, the completed work will be of great value. It is no exaggeration to say that the figures are artistic productions. It too often happens that coloured plates, while giving a perfectly accurate representation of a microscopic section, fail to reproduce the elements of beauty that are always present to the eye of the artist, and upon which a real likeness greatly depends. On the other hand, if the artist, however skilful, is not also a pathologist, it is an almost universal experience that what may

be called the pathological likeness fails to satisfy. Neither of these defects is observable in these plates, a result which is due, not only to the technical excellence of the reproduction, but also to the fact that the pathologists are their own artists, and have had at heart both artistic effect and scientific accuracy. As a consequence of this combination of qualities the figures produce an impression almost identical with that of an actual section, as is well seen in Bazy's figure of chorion-epithelioma. Accompanying the plates is a general histological description of the tumours and of their tendency to extension and generalization. With regard to the execution of the work, it has been arranged that each of the twenty-seven members of the committee shall undertake the illustration of one organ or tissue, while collaborating in all parts of the work for the provision of the best possible preparations and deciding upon the most representative sections.

#### LEMON JUICE AND LIME JUICE.

It will, we believe, be a surprise to many to learn that an antiscorbutic no longer forms part of the regular dietary of the Royal Navy. Probably in these days of short voyages, when a vessel is seldom more than a few weeks away from a port, this does not greatly matter; but it is rather disconcerting to know that the Admiralty relied for many years on the antiscorbutic properties of lime juice. They are very low, and the Nares polar expedition in 1875 suffered severely in consequence. What then happened was almost of the nature of a scientific experiment, for, as Sir Percy Bassett-Smith reminds us in his letter published this week (p. 385), one of the ships was supplied with lemon juice and had very few cases of scurvy. During the war the clinical evidence that lime juice is inferior to lemon juice as a preventive of scurvy was conclusive, and it was confirmed by experiments at the Lister Institute and at the Royal Naval Hospital, Greenwich. Sir Percy Bassett-Smith then succeeded in devising an evaporated lemon juice which could be made up into tablets each containing the equivalent of half a lemon, and kept well. When and why lemon juice, recommended by Lind in the middle of the eighteenth century, and forced upon the Admiralty by Blane at its end, was abandoned for lime juice nobody seems to know; but in spite of all that was learnt before and during the war the Admiralty continues to issue lime juice and not lemon juice, although it now admits that lime juice is not an antiscorbutic, and issues it merely as a temperance beverage which many people find palatable. So long as the Admiralty remembers that it is not an antiscorbutic this, as has been said, probably matters very little nowadays, except in special circumstances. Such circumstances are sometimes afforded by vessels stationed in the Persian Gulf, and certainly might easily arise in any expedition to the Arctic or Antarctic. The memory of the Admiralty is said to be long; we hope it will prove to be so in this instance.

#### "PHYSIOLOGICAL ABSTRACTS."

*Physiological Abstracts* is the title of a journal published monthly by the Physiological Society of Great Britain and Ireland in order to present promptly and in a concise form abstracts of papers published throughout the world in journals of physiology and the allied sciences. Some idea of the huge extent of physiological literature at the present day may be gathered from the statement that abstracts are taken from about 250 journals, and that the total number of abstracts in the yearly volume is about 5,000. The work is done by fifty abstractors, each an authority on the particular kind of original work dealt with. The abstracts are grouped into twenty-three sections, so that a note on an original paper on any subject can be readily found. Each number has an author index, and a complete author

<sup>1</sup> *Atlas du Cancer*. Par L. Bazy et A. Peyron. Deuxième Fascicule (Juin, 1923). Paris: F. Alcan. 1923. (9½ x 12½, not numbered; 5 plates. Fr. 25.)

and subject index is published in the March number in each year. Volume X begins with the issue of next April. The price of a single number is 5s.; the annual subscription is 42s., payable to Messrs. H. K. Lewis and Co., 23, Gower Place, London, W.C.1, or payment may be made through any bookseller. Back numbers can in most cases be supplied, but an extra charge is made for some the stock of which is nearly exhausted. The value of the publication in enabling workers in biological and medical sciences to keep abreast of contemporary research is great, and is, we believe, fully appreciated by them. The periodical is included among those filed in the Library of the British Medical Association.

#### LECTURES AT THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

THE courses of spring lectures at the Royal College of Physicians of London will begin on March 5th, when Dr. Salisbury MacNalty (medical officer, Ministry of Health) will give the first of a course of three Milroy Lectures on epidemic diseases of the central nervous system. Dr. J. A. Rylo (Guy's Hospital) will deliver the first of his Goulstonian Lectures, on the study of gastric function in health and disease, on March 17th. Dr. Hector Cameron (Guy's Hospital) commences his Lancelian Lectures, on some forms of vomiting in infancy, on March 26th. The Oliver-Sharpey Lectures, on the interpretation of the electromyogram, will be given by Dr. E. D. Adrian, F.R.S. (University lecturer in physiology, Cambridge), on May 5th and 7th. The first of the course of four Croonian Lectures by Dr. S. A. Kinnier Wilson will be delivered on June 9th; the subject is disorders of motility and of muscle tone, with special reference to the corpus striatum. The lectures will be given at 5 o'clock on each day. Any member of the medical profession will be admitted to any of the lectures on presentation of a visiting card.

THE Lettsomian Lecturer before the Medical Society of London this year is Sir Bernard Spilsbury, whose subject is "Wounds and other injuries in their medico-legal aspect." In the first lecture, delivered on February 16th, he discussed bruises, crushing injuries of the chest and abdomen, and wounding by firearms. The second lecture, on Wednesday, March 4th, will deal with incised wounds and punctured or stab wounds; the third, on Monday, March 16th, with fractures of the skull. The lectures will be given at 9 p.m. at the house of the society (11, Chandos Street, Cavendish Square, W.).

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### Ministry of Health.

No bills on medical subjects or on public health have come under discussion in the House of Commons as yet, and the Supplementary Estimates for the Ministry of Health were passed without any mention of the health services, a long debate being occupied solely with housing. A token vote of £10 for the Ministry of Health covered an additional grant in aid of £650,000 for medical benefit, sickness and maternity benefits, and other expenditure under the National Health Insurance Acts. The expenditure was offset by savings which included £54,000 anticipated saving on maternity and child welfare, £55,000 on the treatment of tuberculosis, and £48,000 on the treatment of venereal diseases.

Sir John Gilmour, the Secretary for Scotland, has introduced a Public Health (Scotland) Amendment Bill to authorize local authorities to make arrangements for providing medicines and treatment to persons suffering from diabetes, and for purposes connected therewith. Its purpose is to ensure the legality of the supply of insulin by public bodies.

Bills presented by private members include a Sale of Food and Drugs Act (1875) Amendment Bill, to regulate the liability of

milk producers in respect of milk adulteration, supported by a group of agricultural members. There is also a Public Health Bill, to amend the Public Health Acts, 1875 to 1907, and the Baths and Washhouses Acts, 1816 to 1823, in respect of matters for which provision is commonly made in local Acts, and for other purposes relating to the public health, presented by Mr. Womersley (U., Grimsby).

#### Medical Committee.

The Medical Committee of the House of Commons, which has been joined by Dr. Vernon Davies (U., Royston) and Mr. H. Haslam, D.Sc. (U., Newcastle), a bacteriologist, will meet on Monday to discuss the Nursing Homes (Registration) Bill which Mr. Gerald Hurst (U., Moss Side) is to introduce on the following day. The bill has been prepared by the College of Nursing. Mr. Hurst will attend the meeting to explain its proposals to the Medical Committee, and Dr. Cates, the county medical officer for Surrey, will also attend.

#### Salaries of Medical Officers of Health.

Mr. Albery (U., Gravesend), on February 12th, asked the Minister of Health whether his attention had been called to the controversy affecting the scale of payment of medical officers of health; whether he was aware that friction had already arisen with the British Medical Association on the subject; and whether he would consider, to avoid these disputes, the fixing of a scale of salaries which would be agreeable both to the local authorities and to the medical profession. Mr. Groves (Lab., Stratford) and Mr. Evan Davies (Lab., Eltham Vale) further asked the Minister to consider the calling of a conference between the representatives of local authorities, the British Medical Association, and the Ministry of Health with a view to arriving at an agreed scale of remuneration for medical officers of health. The Minister of Health replied that discussions had taken place on this subject between representatives of these interests, and certain suggestions had been made which were still under consideration. He did not think that any useful purpose would be served by calling a conference at present. Further inquiries on the same subject were put down by Major Steel (U., Ashford) and Mr. Robert Wilson (Lab., Jarrow).

**Pensions Medical Officers.**—Major Tryon said, in reply to a question, that the chief considerations in determining the continued employment of medical officers in the Ministry of Pensions were efficiency and the possession of the necessary qualifications for the duties to be performed. Subject to these conditions preference was given to a medical officer with overseas service, more especially if he had a war disability. Out of 378 whole-time medical officers of the Ministry of Pensions 263 had served overseas.

**Public Health Salaries in Scotland.**—Sir Robert Hutchison (L., Montrose) asked the Secretary for Scotland if he was aware that the grant given by the Government towards the salaries and expenses of medical officers of health and sanitary inspectors in Scotland was less than the grant given towards these officers in England; and whether he would see that Scotland got a grant equal to that given in England for this purpose. Sir John Gilmour replied that the difference between Scotland and England arose from the fact that in Scotland the statutory provisions which regulated the distribution of the sums paid into the Local Taxation Account appropriated a fixed annual sum of £15,000 in aid of the cost of medical officers and sanitary inspectors. In England a grant of 10s. per £1 was paid on approved expenditure. The Scottish scheme of distribution could only be revised by Act of Parliament.

**Tuberculosis.**—In a written answer the Minister of Health has stated that in 1921 71,702 cases of tuberculosis were notified in England and Wales, in 1922 69,259, and in 1923 79,388. The last figure included cases not officially notified. On January 1st, 1923, there were 20,629 beds in approved residential institutions and 15,563 persons received treatment from local authorities in such institutions. On January 1st, 1924, there were 21,419 beds and 16,918 persons received treatment; on January 1st, 1925, 22,088 beds and 18,158 persons. In 1923, the last year for which returns were available, the death rate from all causes per 1,000 persons was 11.582, and from all forms of tuberculosis, per 1,000 persons, 1.062.

**Polygythæmia.**—In reply to a question by Colonel Wedgwood (Lab., Newcastle-under-Lyme) about the occurrence of polygythæmia in direct connexion with workers in ammonium sulphate, the Home Secretary said that he had heard of only one case of this disease, the cause of which was obscure, and there was no information to justify its being classed as an industrial disease. He did not want to add to the number of scheduled diseases.

#### Notes in Brief.

The total estimated increase in population of England and Wales from the armistice to December, 1924, is 1,402,000.

It is not likely that special facilities will be given this session for the passage of a bill requiring manufactured food to be labelled with full details of its ingredients.

The question of introducing a scheme of compensation for the grinding trades to cover silicosis, or silica poisoning, as it is known, has been referred to the Ministry of Health for consideration as compensation for silicosis. No further action is expected.

The Government is not prepared to support an appeal to the Spanish and French Governments to give facilities for sending a medical mission and medical supplies to the Rif.

## THE HUNTERIAN FESTIVAL OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

### THE ORATION.

JOHN HUNTER A MARTYR TO SCIENCE.

SIR D'AREY POWER, K.B.E., delivered the Hunterian Oration at the Royal College of Surgeons of England last Saturday, February 14th, the anniversary of the birth of John Hunter. The President, Sir JOHN BLAND-SUTTON, was in the chair.

The orator first discussed Hunter's limitations, remarking that these were partly personal and partly due to the backward state of chemistry, physics, and physiology at the time. Writing to Jenner in 1777, Hunter was careful to explain the exact method of using a thermometer which registered by means of a movable scale of ivory attached to the stem of the instrument. But even with such an imperfect instrument he gave the first correct explanation of the cause of animal heat when he stated that "the blood has an ultimate standard heat in itself in health and nothing can increase that heat but some universal constitutional affection." He thus gave the death-blow to "calidum innatum," but missed the opportunity of putting the thermometer to practical use as a measure of fever in the body.

Examples were given of the shifts to which John Hunter was put in order to explain the causes of disease in his ignorance of the part played by micro-organisms. The statement that "true specific disease is one that probably cannot arise but only from one cause and which probably always belongs only to morbid poisons" made it clear that he had some premonition of the real cause, for he gave as an example "scrofula, which is one of those diseases which is supposed to be hereditary; but it is only a readiness to fall into a peculiar action when properly irritated that is hereditary, and when such a cause does not exist we find no scrofula." Surely, said the orator, "nil nisi clavus deest": the key alone is wanting, and the key was not forged until Pasteur and Lister—the master locksmiths of the nineteenth century—came to maturity more than seventy years after John Hunter's death. He was even a little in advance of Lister's early work, for he showed by experiment that "air simply has no power to excite inflammation."

The origin and growth of the Hunterian school were then traced. It began from a desire on the part of surgeons for better teaching than was provided by the United Company of Barber-Surgeons. It spread rapidly as a result of the personal magnetism of John Hunter, who was known to his pupils as "the Dear Man." These pupils were a small band of young men who afterwards became the leaders of surgical thought in England and in America. Sir William Blizard, Sir Astley Cooper, William Hey, John Abernethy, Philip Syng Physick, and John Syng Dorsey in the first generation; Sir Benjamin Brodie, Sir William Lawrence, John Collins Warren, and Valentine Mott in the second; Sir James Paget and Sir William Savory in the third; Professor S. G. Shattock and Sir Arthur Keith amongst ourselves.

Attention was drawn to the physical disabilities under which John Hunter laboured during the last twenty years of his life—disabilities which were the direct outcome of the venereal poison with which he deliberately infected himself to determine whether syphilis and gonorrhoea were due to the same cause. His health began to fail from the time of the inoculation, until during the last eight years of his life he had daily attacks of angina pectoris, often associated with symptoms of syphilitic disease of the brain. His courage was dauntless and his intellectual faculties were so little impaired that he continued to give sound judgements in consultation, to invent new operations in surgery, and to collect the specimens which are now housed in the magnificent museum of the College.

Hunter being dead still speaketh, continued Sir D'Arcy Power, and his work has been crowned since the last oration was delivered by the genius of Professor Elliott C. Cutler—a young American—who has subdued the diseased heart to

the hand of the surgeon by the successful removal of portions of the valves in mitral stenosis.

The oration ended with brief eulogies of surgeons who have died lately. Sir William MacEwen, a pioneer in the surgery of the brain, lung, and bone. Sir Frederick Treves, who took upon himself the heavy responsibility of postponing at the last moment the coronation of King Edward VII. Professor S. G. Shattock, the humble-minded disciple of John Hunter. Sir Alfred Pearce Gould, the friend and helper of all who had fallen on evil days. Mr. Harrison Cripps, who possessed the rare combination of first-rate business capacity, great powers of administration, and high surgical skill. Sir Charles Ryall, genial and trustworthy. Sir William Thorburn, the exponent in England of the surgery of the spinal cord, dead at the very moment when he was beginning a life of leisure, saddened by the domestic afflictions which the war brought to him. Nor did Sir D'Arcy Power forget to mention Mr. G. P. Newbolt, Mr. R. A. Bickersteth, and Mr. George Heaton, pupils of his own who so worthily upheld the position of surgery in Liverpool and Birmingham.

A series of lantern slides were exhibited, after the oration, made from water-colour sketches by Jesse Foot, who wrote a scurrilous life of John Hunter. They showed Hunter as he appeared to his contemporaries and not as he was idealized by Sir Joshua Reynolds. Sir D'Arcy Power stated that he was indebted to Mr. C. J. S. Thompson, M.B.E., for permission to show the drawings, which are contained in a book in the possession of the Wellcome Historical Museum.

### THE BANQUET.

In the evening the President and Council entertained a large party to dinner in the library of the College.

After dinner the Lord Chief Justice of England, in proposing the toast of "The Royal College of Surgeons of England," compared in light vein the two great professions of surgery and of the law, and in sketching their early history said that it might be difficult to prove his belief that though surgery was very old, law was slightly older still. Then, becoming more serious, he said that surgery and law resembled each other in this, that their practitioners were called in emergencies; but there was a difference, which was in favour of the law. The lawyer, at any rate, was not suddenly called upon, in a case which seemed likely to be fatal, to do the best he could then and there, on the spur of the moment, with the high probability that death might follow, "and with the distinct risk that there might be a prosecution for negligence."

The President (Sir John Bland-Sutton) also began his reply in light spirit, suggesting that the connexion between the profession which the surgeon so humbly followed and that which Lord Hewart so eminently adorned was, from the point of view of the anatomist, as direct as the hangman's rope, which in the past had furnished surgeons with subjects for anatomical dissection. He then turned to the Museum and its conservators, and recalled how Richard Owen had from a fragment of bone reconstructed, with extraordinary accuracy, a creature the skeleton of which was only much later discovered. Sir John Bland-Sutton recalled the famous passage from Ezekiel about the valley full of dry bones: how God directed the prophet to prophesy upon the bones, and how, when the prophet obeyed, there were shakings and the bones came together, bone to his bone, and the sinews and the flesh came upon them, and the skin covered them. Then, passing to Job, the President recalled the rhapsody about behemoth: how his bones were strong, were as strong pieces of brass, like bars of iron. The Royal College of Surgeons possessed a great collection of bones, and much had been learnt from their study by succeeding conservators; but the collection had never been better or more sanely handled than by the present conservator, Sir Arthur Keith, who possessed the sagacity of Owen, the imagination of Ezekiel, and the rhetoric of Job.

The toast of "The Guests" was given by Sir HOLMUR WARRING, one of the vice-presidents, who, after sketching the growth of the Museum, expressed the hope that the Historical Section would expand, and mentioned incidentally that the guests would be able to see after dinner a rib

of King Robert the Bruce, showing that it had at some time been fractured in the place where such an injury most commonly happens—the convex part of the body. The toast was acknowledged by the SPEAKER of the House of Commons. The toast of "The Orator" was given by the Rev. Dr. NAIN, and acknowledged by Sir D'ARCY POWER.

#### A Portrait.

Afterwards the guests had the opportunity of seeing a number of specimens of historical interest, including some presented to the College by Sir Astley Cooper. In the conservator's room there was displayed a portrait, said to be of John Hunter and to have been painted by Thomas Gainsborough; but these attributions have not been definitely established in respect of either the subject or the artist. It is certainly a very lifelike portrait, three-quarter length, full face, with the lips parted as though speaking. The figure holds a monkey's skull in the left hand. The face is that of a man past middle age, with a fresh complexion and scanty hair, very full of life and vigour, and evidently very earnest in what he is telling his audience—a very different Hunter from the inspired prophet of the Reynolds portrait; but those so minded could trace a resemblance to the face of the well known portrait of Hunter with the head of his wolf-dog on his knee, a copy of which had been hung beside it.

## TRAFFIC DANGERS AND A REMEDY.

BY  
CHARLES BUTTAR, M.D.

THE dangers in traffic which arise from the increase in motor driving have an interest for members of the medical profession, for probably a large majority now drive a motor vehicle of some kind, and so are exposed to motoring accidents. As the Government is contemplating a new Road Bill, which will probably supersede to some extent the Motor Car Acts, it would be well for a profession which is closely in touch with the use of motor cars, and is concerned also in remedying the accidents arising therefrom, to consider whether its experience may not be of some use in the moulding of the bill.

When the Motor Car Act of 1903 was framed most people were quite unaccustomed to speed on the public roads, and speed was regarded as the main source of danger. It was useless for the motorist to urge that at a given speed his car could be pulled up in half the distance in which it was possible to stop a hansom cab. The bugbear was the speed of these new-fangled vehicles, and a speed limit was introduced to satisfy the nervousness of the public. The concession of a limit of twenty miles an hour was regarded as most generous, considering that previously all mechanically propelled vehicles had been compelled to crawl behind a man on foot carrying a red flag. In certain places this limit was reduced by half, so that theoretically it was possible for an easily controlled vehicle that could be stopped in half the distance to be passed by a trotting horse or by a bicyclist. The public has probably learnt by now that speed in itself is not necessarily a danger; yet the dangers of the street are very real. If rumour speaks the truth, it is now proposed to abolish the speed limit, and to base charges against motorists solely on the ground of "danger to the public."

The charge of driving to the danger of the public will be brought by a policeman, who in most cases will be quite untrained in motor driving. Have the authorities who are drafting the Road Bill asked how the policeman will form his opinion of danger, and whether the magistrate will have any criterion on which to form a judgement on the evidence? After twenty-three years of motor car driving, during which period I have covered about 150,000 miles in London, and have observed many accidents in which a motor vehicle has been involved, I am convinced that no standard is recognized by which dangerous driving can be gauged. It seems probable, therefore, that the new bill may propose to inflict a great deal of injustice on motorists; and this injustice will result from the fact that there is practically no rule in existence for street users, whether

drivers or pedestrians. The only semblance of a rule is the convention that vehicles in this country, when passing one another in opposite directions, keep to the left-hand or near side of the road.

Since there is no rule for street traffic in any way comparable to the rules laid down for ships at sea, it would appear that the only rule observed by the drivers of motor vehicles is that the first man in gets the prior right to the road. This leads to all sorts of misbehaviour—and possible danger—such as cutting in from the near side, turning corners without observing if the road is clear, crossing roads without regard to oncoming traffic, and so on. Yet in any of these contingencies it should be possible to know which person has the right of the road. To meet some of these contingencies another convention has been set up—namely, that traffic from "side roads" should give way to that on "main roads." But very little examination of the roads in London will show that even if this convention is valid to some extent for main road traffic in the country, it is hopeless as a rule for town driving. In countless spots it is impossible for the motorist to know which is the main road and which the side road.

#### The Right-hand Rule.

In searching for ways to reduce the dangers of the street many suggestions have been made, such as signposting side streets, codes of signals by means of the arm and hand, and semaphores. These methods are open to objection either on the score of expense, or of possible misinterpretation of the signals, or because they take no account of pedestrians. In any case they all involve complication. What is wanted is a rule in which the safety of the public is the first object—a rule which is simple, easily taught, and applicable to both drivers and pedestrians. Some years ago such a rule was proposed, and obtained the notice of the writer on motor matters in the *Pell Mell Gazette*. This motoring expert set out to find objections to the rule, or what he called the "limiting case"; and the only limiting case he could discover was one which made the position absolutely safe.

The proposal was that every user of the street should be made responsible primarily for avoiding collision with any car or person on his right hand, so that in the event of an accident the onus should be placed on the person colliding with someone on his right-hand side of showing why he did so. Thus, at cross-roads a driver would wait for, and pass behind, any vehicle approaching from his right; at street crossings a pedestrian would always look first to the right; a driver cutting in from the near side, as so often happens in London, would have to explain his reasons for doing so in the event of accident. The limiting case of the *Pell Mell Gazette* was that if four cars were approaching one another on four cross-roads, all the cars would stop, as each driver would have a car on his right hand. And the reply was that the position was, at all events, safe; and safety is the first object of any rule.

The proposed right-hand or off-side rule in driving is not only safe; it would seem also to fulfil the other requirements named above. It is plainly simple, and anyone who uses it consistently will find that the need for signals, semaphores, or signposts marking side roads will completely disappear. Being simple it is also easily taught. Children in primary schools could easily be taught by repetition to look to the right before crossing roads. As soon as any complications are introduced teaching becomes much harder. The police force can be instructed on the importance of watching for any infraction of the rule when an accident occurs. Motoring schools can teach their pupils. Magistrates and judges can raise the point in any case that is brought before them. A small amount of advertisement, together with a few decisions in the law courts, based on the rule, will speedily teach the public. It has already been mentioned that the rule applies with equal validity to pedestrians and drivers.

#### Order out of Chaos.

Most people are now impressed by the number of casualties which occur annually in the streets. Many people think that there is some sort of code of rules by which motorists drive. But there is no such code in exist-

ice; the decisions of the judges and magistrates are based on no standard; no one has yet defined dangerous driving. The right-hand rule would give a standard and a definition in a very large proportion of cases. It has one disadvantage only: it is so simple that in many minds it arouses suspicion that there is "some catch in it." No rule, of course, can ever completely abolish accidents. But that the right-hand rule can prevent many, if not most, accidents should be plain to anyone who cares to study the circumstances in which a medical man recently lost his life. He was standing on the pavement near the crossing of two roads of equal importance from the traffic point of view. Along one road a lorry approached a small car travelling in the other road. Having no rule in driving except that of the "first man in" having the prior right, neither the lorry nor the car was able to pull up. One vehicle skidded on to the pavement and killed the medical man. Both drivers were arrested, and nobody knew whether either or neither was responsible for the accident. The right-hand rule would have required one of the drivers to account for his action in crossing the bows of the other vehicle; and had both drivers been aware of the rule probably no accident would have occurred. Both would have been careful of taking risks.

Before adopting a definite line of action it is well that every objection should be met. The right-hand rule so far as brought forth no objection except that of the so-called limiting case. With the increase of street accidents it is surely fair that some thought should be given to the proposal, some arguments—if they exist—adduced against its adoption. So strongly do I believe in the rule that I think the only sufferers from it would be the lawyers with fewer cases to defend, the motor repairers with fewer cars to mend, and the doctors with fewer patients to treat, and fewer policemen would be required to control traffic. The public, I am convinced, would gain in safety to life and limb.

## ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

(Continued from page 278.)

PROPOSALS OF THE NATIONAL SOCIETY FOR LUNACY REFORM. The whole of the most recent sittings of the Royal Commission on Lunacy and Mental Disorder on February 9th and 10th was devoted to the further evidence of Mr. MONTGOMERY PARKER, chairman of the National Society for Lunacy Reform. The general submissions which Mr. Parker made to the Commission on behalf of his society were set out in the BRITISH MEDICAL JOURNAL of January 31st (p. 230), and the report of his evidence was continued in the issue of February 7th (p. 277).

Much of the discussion on this occasion related to alleged cruelty in mental institutions. Mr. Parker said that his society had numerous statements from patients which left no room for doubt that on many occasions physical violence took place. The reports of the Board of Control had a constant record of broken ribs and limbs, all of which were accounted for by the Board as resulting from accident, but when no such record was noted the Board claimed that the result was due to the care and kindness of the attendants. But to some extent what he called chemical violence had superseded physical violence, and the use of drugs as a punishment was infinitely harder to detect or prove. Dr. Hubert Bond had stated before the Commission that medical restraint was now largely substituted for mechanical restraint. Some explanation was called for as to the use of hyoscine, an injection of which was described by Dr. Stoddart, in *Mind and its Disorders*, as "a refined substitute for hitting the patient on the head with a club." The report of the Cobb Committee indicated that hyoscine was hardly ever used in certain asylums, but at Prestwich its consumption was heavy (60 tubes were bought in 1919-21, of which 39 were used). He went on to speak of the use of croton oil, the most painful and virulent purgative known. Of 22 hospitals selected by the Cobb Committee for investigation 2 showed large weekly doses, 3 showed smaller doses, and 17 used no croton oil. He begged the Commission to address a questionnaire to all mental institutions, requiring a return of purchases during the last five years. His society had also evidence of systematic restriction of the use of latrines at stated times; this attempt—especially when purgatives had been administered—to regulate the functions of nature by written order and then to punish patients for want of cleanliness, reflected on the mentality of the administration.

On the question of punishment in general Mr. Parker said that he noticed a remarkable silence in the evidence so far given to the Commission. By a process of subtle suggestion one was left to infer that it formed no part of the asylum system. He admitted the necessity of maintaining discipline, but it appeared that in the absence of statutory provision all necessary action directed to this end was left in the hands of the medical staff. As a direct con-

sequence, all the acts so common in the daily life of the sane, such as quarrels, slander, violence, assumed an exaggerated importance in the life of the insane, and instead of being judged on their merits and overlooked or dismissed with a suitable punishment, they went to swell the growing record of bad behaviour which prolonged the detention of the patient. The deplorable effects which must result from combining the functions of medical officer with those of judge and gaoler were self-evident. Punishment was always indefinite, "pending the doctor's pleasure," and this in itself was an irritating and depressing feature. Apparently it took one or more of three forms—loss of privileges; seclusion, generally with confinement to bed; and relegation to an inferior or refractory ward. His society submitted that the practices at present in force for maintaining discipline were in many cases cruel, and, difficult as the subject was, it was an urgent necessity that other means of maintaining discipline should be devised.

With regard to diet, there had been an improvement in recent years, which, the patients said, became apparent soon after Dr. Lomax's disclosures. In spite of official figures it was impossible to believe that bread and margarine for breakfast and the same diet for tea every day of the week was conducive to the restoration of physical and mental health, or that the absence of any food between 4.30 p.m. and breakfast next morning produced a standard of comfort to which the bulk of patients had been accustomed before they became paupers by law. It was admitted, however, that steps had been taken in some asylums to mitigate these conditions. Occupational treatment, again, was very deficient, the opportunities for congenial occupation being very limited.

Finally, Mr. Parker drew attention to the diversity of standards set up. The report of the Royal Commission of 1908 adopted the term, "of unsound mind" as the sole criterion of lunacy, and defined a person of unsound mind as one "who requires care and control owing to disorder of the mind, and is consequently incapable of managing himself or his affairs." This was too vague a term by itself, and in the hands of a medical practitioner was a terrible menace to the liberty of the subject. The society submitted that conduct was the most valuable test of sanity, and that both the criteria adopted in the past by the law—namely, "the capacity to manage himself," and "the safety of the person and the public"—should be applied in all cases of certification; further, that where incapacity extended to a person's affairs only, the detention was not necessary if a receiver was appointed.

The Commission adjourned until February 24th.

## Canada.

[FROM OUR OWN CORRESPONDENT.]

### CANADIAN MEDICAL ASSOCIATION.

THE annual meeting of the Canadian Medical Association will be held in Regina, Saskatchewan, on June 22nd to 26th; the President-Elect is Dr. David Low of Regina. The business meetings of the council will be held on the first two days, and the remaining three will be devoted to the regular medical and surgical programme.

### HOSPITAL ADMINISTRATION.

In October last the first annual convention of the Ontario Hospital Association met in Toronto at the Academy of Medicine; eighty or ninety hospitals sent representatives. Dr. J. J. Walters of Kitchener stated in his paper that in his opinion municipalities should pay the expenses of erecting hospitals so that there should not be the usual hospital deficits. One of the most important suggestions made at the meeting was that a central purchasing bureau should be established for the procuring of supplies at the lowest possible rate, an arrangement which I believe has worked well for the hospitals of London. One speaker considered that the hospital costs for private and semi-private patients (be it remembered that nearly all the hospitals in this country have private and semi-private wards and that nursing homes are uncommon) were far too high. He also disapproved very strongly of the action taken by the Workmen's Compensation Board in refusing to pay extra charges for the use of operating rooms, etc., for workmen treated in the hospitals. It was resolved to send a resolution to the Provincial Secretary protesting against this injustice.

### ROTARY CLUBS AND CHARITABLE WORK.

In recent years Rotary clubs or similar organizations have been established in almost every city of the United States and Canada. The members consist, generally, of a representative from each of the learned professions and of the various forms of business enterprise. The members meet at luncheons and discuss various questions of interest to them all and learn each others' points of view. In a very praiseworthy manner these clubs undertake schemes of charitable work and carry them through with a right good will. A

great deal of good is done by them in this way. The Gyro Club of Calgary, for instance, has recently established and agreed to maintain a clinic for the infants and young children of the poor. The medical work is done by the Calgary Medical Society, aided by the nurses of the Victorian Order. There is a Rotary Club Tuberculosis Clinic in Vancouver, and in Montreal the Kiwanis Club has lately erected a pavilion for the Children's Memorial Hospital to afford additional space for the open-air treatment of surgical tuberculosis and other diseases. The Mystic Shriners, who I believe form a body within the Masonic Order, have also done much, in the same way, on a large scale and have financed the building of a children's hospital in Montreal.

#### MEDICAL STUDENTS IN EASTERN CANADA.

It may be of interest to give the numbers of students in some of the medical schools of Eastern Canada. At Queen's University, Kingston, Ontario, 254 are registered for the session 1924-25. These students are almost equally divided amongst the five years, but none will graduate this year, as the course has been lengthened from five to six years. The last class of the old five-year course obtained their degrees in May, 1924. At the University of Toronto 797 students (68 women and 729 men) are registered. Of these, seven students are seeking the diploma in public health, two the diploma in radiology, three the degree of Bachelor of Science (Med.), and three are doing post-graduate work. At McGill University, Montreal, the medical course lasts for five years, but before admission to the first year the student must have completed two years in a Faculty of Arts or its equivalent. In these two years chemistry (inorganic and organic) must have been studied for two years, and physics and biology each for one year. The total number of students registered for the five years is 490, including a small proportion of women.

#### AMALGAMATION OF MEDICAL JOURNALS.

The *Canada Lancet*, founded in 1866, and the *Canadian Practitioner*, established in 1875, both in Toronto, have been combined under the name of the *Canada Lancet and Practitioner*, the first number of which appeared in January. These journals formerly reflected the opinions of the two medical schools—Trinity Medical School and the Toronto School of Medicine. These schools were amalgamated several years ago, so it is very fitting that their publications should combine. The editorial board, largely composed of those on the staff of the old journals, is a strong one. Problems of preventive medicine and of the various branches of hygiene, rather than those of general medicine, will be treated in this journal. The veteran Dr. Adam H. Wright is one of the editors, but his companion in the *Practitioner*, Dr. W. H. B. Aikins of Toronto, who died last October, at the age of 65, will be sadly missed. Dr. Aikins came of a family many of the members of which distinguished themselves in their various callings. He was educated in Toronto at Upper Canada College, and graduated in medicine there; later he studied in New York, the British Isles, and Europe. He was an active worker in the various medical associations in Canada and acted as secretary for Canada at the International Medical Congresses held in Lisbon, Budapest, and London. He was one of the first here to recognize the value of radium in medicine, and at one time was president of the American Radium Society.

#### CANADIAN NATIONAL COMMITTEE FOR MENTAL HYGIENE.

Six years ago the Canadian National Committee for Mental Hygiene was formed, and its annual meeting was held at Montreal on November 14th, 1924. At the meeting of the board of directors it was decided to devote 30,000 dollars a year for five years to research studies, particularly in Toronto and Montreal. An energetic educational programme will also be carried out. Her Excellency Lady Byng of Vimy early identified herself with the work, and the Lady Byng of Vimy Fund has now reached the sum of 275,000 dollars, 200,000 dollars being subscribed by Canadian citizens and 75,000 dollars generously given by the Rockefeller Foundation.

At the general meeting open to the public the President, Dr. Charles F. Martin, outlined the work already done,

which included raising the standard of treatment and care of those who are mentally abnormal, the institution of preventive measures, the stimulating of universities to greater interest in educating teachers, students, social workers, and the public generally, and the introduction of the principles of mental hygiene into schools, reformatories, gaols, hospitals, and courts. He said that the Government had been educated in the importance of all these problems, and improved methods of immigration had been introduced by insisting upon better examination of those entering Canada. Most important was the formation in the secondary schools of classes for the mentally defective. Mr. E. R. Embree, secretary of the Rockefeller Foundation, spoke of what could be done in the future by the study of feeble-mindedness, especially in the child. Sir Arthur Currie, Principal of McGill University, said that the University was doing all it could to forward the movement, and that several members of its staff were investigating the problems of mental hygiene, their work being supported partly from the funds of the University and partly by funds allocated by the Committee. Dr. C. F. Martin was re-elected president, and Dr. C. M. Hincks was elected the medical director.

## India.

#### INDIAN LEPROSY CAMPAIGN.

The Viceroy, Lord Reading, has appealed for funds to provide the Indian Council of the British Empire Leprosy Relief Association with the means to organize an attack on leprosy with a view to its elimination. In a speech on January 27th he laid emphasis on the need for research, the establishment of out-patient clinics, and improvements in leper institutions. A strong general committee for the whole of India has been appointed under the chairmanship of Sir Frederick Whyte, and generous support by the newspapers and the people generally appears assured.

#### TREATMENT OF RABIES AT LAHORE AND IN WESTERN INDIA.

It is announced that antirabic treatment is now available at the Punjab Bacteriological Laboratory in Lahore throughout the year, of a similar kind to that given at the Pasteur Institute at Kasauli, Coonoor, and Shillong. The course of treatment ordinarily lasts about a fortnight, during which the patients are confined to bed. No in-patients are received at the laboratory, but any in a serious state of health, as a result of wounds or other causes, can be treated in the Mayo Hospital, Lahore. The antirabic treatment is given free, and railway concessions are granted to Government servants and necessitous patients unconnected with Government service. The agent to the Governor-General in the States of Western India has issued a notification that from January 8th a centre for antirabic treatment will be opened at the West Hospital, Rajkot. The need for this has long been felt in view of the many cases of disease occurring in Kathiawar. Until the opening of the rather nearer station at Ahmedabad patients were required to travel to such distant treatment centres as Kasauli.

#### PUNJAB SCHOOL OF MEDICINE FOR WOMEN.

The new maternity block of the Memorial Hospital for Women and Children, Ludhiana, which is connected with the Women's Christian Medical College and the Punjab School of Medicine for Women, was opened recently by Lady Hailey. The principal of the college, Dr. Edith Brown, explained that a gift of 80,000 rupees from the Punjab Government had made the building of this new block possible. The addition provides seven private wards and three free wards, accommodating altogether twenty-four patients. During last year the in-patients numbered over 2,000, and more than 78,000 visits were paid by out-patients. Patients came not only from the Punjab but from all parts of India, and some even from Burma, Persia, and Africa. The hospital and college trained Indian women as doctors, nurses, compounders, and midwives for the whole of the Punjab, and for other parts of India.

Since 1900 134 medical practitioners, 100 nurses, and many compounders and midwives have received their education in the college.

#### BURMESE INSTITUTE OF PUBLIC HEALTH.

The Governor of Burma, when laying the foundation stone of the Burmese Institute of Public Health, dwelt on the urgent need of a progressive public health policy. Hitherto, he said, the advantages of preventive medicine had been insufficiently appreciated in Burma, even though the majority of the population showed signs of a strong natural inclination towards personal hygiene and cleanliness in the home; with the expansion of this existing interest in personal hygiene into community hygiene, the way for a great advance in public health would be prepared. The new institute will provide a training school for the public health service, a provincial public health laboratory, and an institute for research in public health problems. Moreover, it is proposed that the institute shall serve as a centre for the dissemination of instruction in health matters, and as a meeting place for the various societies interested in public health propaganda. The institute will also help in obtaining for Burma the much needed legislation with regard to adulteration of food and drugs. The Governor referred to the recent formation of a public health advisory board for Burma, and to the steps taken to combat venereal disease and leprosy, both very prevalent in the country. He added that a medical committee was at present engaged in investigating the conditions of leper asylums with a view to improving their administration and the treatment of the disease.

### Ireland.

#### FREE STATE MEDICAL BILL PASSED THROUGH FINAL STAGES.

THE SENATE of the Irish Free State considered last week the committee stage of the Medical Bill (1924), which provides for the continuance of the existing arrangements for medical registration. Mr. P. McGilligan (National University), Minister for Industry and Commerce, said the bill was only a temporary measure, covering a period of twelve months. The object of the bill was to enable Irish medical practitioners to have their names inserted on the *British Medical Register*. The delay in connexion with the bill was due to prolonged negotiations between the British and Irish Governments in reference to some points in dispute. It was decided and agreed that legislation should be introduced both in Dublin and at Westminster. That legislation would not be identical. He had recently received two intimations—one from the Irish Medical Council, that it desired that the Irish bill should become law before February 23rd; the other communication was from the British Colonial Office, to the effect that the point that had been in dispute was no longer in dispute. In the circumstances he felt it was necessary and right to meet for the purpose of getting the bill passed, so that it would become law on February 23rd. Senator Dr. Gogarty said that the sooner the position of the medical profession was defined and legalized the better. Behind the whole matter lay the question whether or not the medical profession in Ireland, and those entering it, should have the right to practise in any part of the British Empire. When the contribution that Ireland had made to the empire was considered, it was not a matter of "saving faces," but a matter of asserting a right. If the bill were not rapidly put through the Oireachtas, Free State medical students would be no longer entitled to exercise freely their rights in the British Empire. If they did not have that right it would mean debasing the degrees of Irish colleges and the closing of them eventually. The ordinary wear and tear of the profession in the Irish Free State depleted the ranks by about twenty every year, whereas the medical institutions turned out about 150 qualified men every year.

The bill passed through all its stages, and now only awaits the signature of the Governor-General. The bill authorizes the General Medical Council to continue temporarily to exercise authority in respect of medical practitioners in the Irish Free State. Persons registered under the Medical

Acts are, in the Saorstát, to have the same rights, privileges, and immunities, and be subject to the same obligations as in Ireland before the Saorstát came into existence. The General Medical Council is to have, in relation to persons and matters in the Saorstát, all the old powers, jurisdictions, and authorities; the Branch Council for Ireland will similarly retain its powers; the General Council and the Branch Council will continue to be constituted and elected as before; and universities and medical corporations in the Saorstát continue to have powers of granting diplomas and holding qualifying examinations under the Medical Acts.

### Scotland.

#### GLASGOW ROYAL INFIRMARY: SUGGESTED EXTENSIONS.

AT the annual general meeting of the Glasgow Royal Infirmary Lord Provost Montgomery presided and moved the adoption of the annual report. Mr. James Macfarlane, LL.D., chairman of the board, stated that the subject of greatest concern to the managers was the congestion of wards and the long list of patients waiting admission. As this affected hospitals throughout the country, it was really a matter of national importance and urgency. There had been a suggestion that another infirmary should be added to the three already in existence in Glasgow, but in his opinion before this was carried out care should be taken to see that the fullest advantage was taken of those already in existence. He would therefore suggest that the present pressure could be relieved, in the first place, by the erection of an auxiliary or convalescent hospital outside the city to which cases might be removed after short treatment in the general hospitals. Secondly, he thought a fully equipped nursing home should be established for the accommodation and treatment of patients who could pay the charge necessary to cover the cost of running the home although they could not afford the expense of an ordinary nursing home. Professor Glaister, who moved a vote of thanks to the medical and surgical staffs, also stated his opinion that there was clamant need for the institution of a nursing home situated in the open country which could relieve the pressure on the wards at the Royal Infirmary by the transfer to it of patients after the critical period of their illness had passed. In the annual report it was stated that 13,969 patients had been treated in the wards during the past year, an increase of 1,210 on the figures of the previous year. The daily average number of patients was 726.6, and the average period of residence nineteen days. In the out-patient department 51,954 patients had been treated, an increase of 3,261 as compared with the previous year; the total number of attendances had been 235,570, as compared with 220,193 in the previous year. At the Ophthalmic Institution connected with the hospital 919 in-patients and 15,424 out-patients had been treated. Mention was made of the prospective formation in the infirmary of a new biochemical department for investigation and research in relation to disease, towards the expense of which donations had been given of £5,000 by the executors of the late Dr. F. H. Clarke, Dumfries, and £500 from the executors of the late Mr. F. L. O. Rottenburg. The ordinary expenditure had been £110,194 and the ordinary revenue £85,189. An exceptional sum of £100,143 had been derived during the past year from legacies, and this sum had been drawn upon to meet the deficit on ordinary expenditure as well as to provide for the extraordinary expenditure of £3,739. Out of the surplus £30,000 will be devoted to the reconstruction fund. Mr. D. Bruce Warren, son of the retiring treasurer, was appointed honorary treasurer in succession to Mr. Timothy Warren, who had held this position for twenty-five years.

#### EDUCATIONAL PROGRESS IN VETERINARY SCIENCE.

At a meeting of the Scottish division of the National Veterinary Medical Association held at the Royal (Dick) Veterinary College, Edinburgh, Principal Charnock Bradley, who presided, delivered an address. He said that the war had very clearly demonstrated the national value of veterinary science in times of peace. The eyes of the public had

been opened to the bearing which land cultivation and animal husbandry had upon national well-being. There was an increasing number of members of the veterinary profession who did not follow general practice, and the schools now offered facilities for specialized training and for those seeking official appointments. The last sixteen or twenty years had seen advances greater than any that had occurred since veterinary education was first established in Great Britain. Real education had been made more natural and the student was asked to verify facts for himself, so far as circumstances permitted, and not merely to listen. This, however, could not be effected with the institutional equipment formerly provided. The institution of post-graduate distinctions, such as university degrees and diplomas of veterinary State medicine, would exert a growing influence upon the veterinary profession as a whole, and slowly but surely the time was coming when the possession of post-graduate distinctions would be indispensable for candidates for appointments. The primary duty of an institution like a medical or veterinary school was so to train students as to make them proficient in a professional capacity, but the medical or veterinary school ought to do more. No profession could afford to rest solely on the professional performances of its members, and it must be impressed upon the public that the profession had an atmosphere and a dignity as well as an achievement.

## England and Wales.

### WEST LONDON HOSPITAL EXTENSION.

ON February 10th Princess Mary opened a new wing at the West London Hospital, Hammersmith. The chairman of the hospital, Mr. Reginald E. Watson, announced that this addition provided a further 60 beds, bringing the number now available up to 220. The new accident ward contained 16 beds, and, in addition to two cancer wards containing 7 beds, and two new operating theatres, a block of twenty private rooms has been erected to accommodate twenty-two paying patients. The whole of the new wing was opened entirely free of debt, money for the cancer wards having been provided by Mrs. Hull Martin, whilst Mr. Dan Mason had contributed £20,000 and the cost of the equipment of the private wards. In the course of the ceremony the Countess of Ilchester presented a cheque for £1,100, on behalf of the Ladies' Association, to endow the Princess Mary bed in the Hull Martin ward. It was announced that a second bed in the ward had been endowed by Mr. Charles Pascell.

### PUBLIC HEALTH IN LIVERPOOL.

At a meeting of the Liverpool Medical Institution on February 12th, Dr. E. W. Hope gave an account of the sanitary advances of Liverpool and of the measures taken to ameliorate the conditions resulting from the singularly rapid growth of the city at a time when sanitation was very imperfectly understood and when no legislative powers existed to check or remove the rapidly growing evils. Much of the earlier local legislation had formed the basis of the Public Health Acts of the country, but the sanitary needs of Liverpool had made necessary many applications to Parliament. The great housing operations, both within the city and in its outskirts, were illustrated, as well as the measures which led to the present unstinted supply of water, transported from the purest sources sixty miles away. It was available for delivery to every floor in every house at the moderate cost of 1½d. a ton. The steps which led to the establishment of the present efficient hospital and sanatorium system were traced, and it was pointed out that the term "infectious hospital," as applied to properly spaced institutions upon an area of some 200 acres, had a very different significance from that applied to hospitals of half a century ago. A description was also given of the development of the individual as well as of his environment. Hygiene, the uses of health visitors, ante-natal and post-natal centres, maternity homes, infant welfare centres, control of food supplies, and other important accessories were dealt with. With a view to making sanitary problems intelligible and interesting to the general public the University School of Hygiene had been established.

### MANCHESTER ROYAL INFIRMARY.

At the annual meeting, on February 13th, of the Manchester Royal Infirmary attention was drawn to the present rather anxious financial position. The deficit for 1924 was £24,147, compared with £12,300 in the previous year. The combined income of the infirmary and the Barnes Convalescent Hospital during 1924 was £87,000, as compared with £85,000 in 1923; whereas the expenditure in 1924 was £113,011, compared with £103,894 in 1923. The total number of patients treated has decreased from 61,032 in 1923 to 54,734 in the year under review; but a striking feature of the report is the steady increase in the number of casualties treated in the accident rooms, though not admitted as in-patients. This number has increased from 18,000 in 1921 to 24,000 in 1924. The annual report of the board includes a statement of the desirability of increasing the number of nurses as soon as may be possible, so that the present working hours of sixty-three a week for those engaged on day work, and seventy-three for those engaged on night duty, may be reduced to an all-round week of fifty-six hours. For this purpose extra accommodation is required for seventy additional probationers and thirty maidservants. Accommodation is also necessary for the massage school, which is at present housed in temporary premises. The cost of this additional housing will amount to £50,000 at least; and the board feels that adequate funds ought to be raised for the large extra annual expenditure.

### L.C.C. SLUM CLEARANCE SCHEMES.

The latest addition to the housing programme which the London County Council has undertaken, involving the displacement and rehousing of 2,700 persons in the Oulton Street area of St. Pancras, was referred to in a leading article in our last issue (p. 320). The programme of the Council now embraces slum clearance schemes in nineteen areas, situated in eleven boroughs, but chiefly in Southwark, Shoreditch, and Stepney. The total area to be cleared is 88 acres, the number of persons who have already been or will be displaced is 25,168, and of these the Council is under an obligation to rehouse 23,000. The total estimated cost of the clearance and roadwork, not including the provision of the rehousing accommodation, is £1,145,200. The Council has also in hand a number of building schemes at Becontree, Downham, Roehampton, Hendon, and elsewhere. The number of houses still to be erected under these schemes, and for which specific provision has been made in the estimates, is 12,194, all for letting at weekly rents.

### TRAINING OF HEALTH VISITORS.

Brief mention was made in our last issue of a memorandum issued by the Ministry of Health giving details of the grants to be made for the training of health visitors in connexion with the decision that, after April 1st, 1928, no first appointment as a whole-time officer of a local authority, with health visiting duties, will be made unless the candidate has obtained a certificate from a recognized central examination body. For the purpose of the grant it has been decided to approve, in the case of a trained nurse, a whole-time course of training in public health work lasting for a minimum period of six months, and normally covering two academic terms. Students who are not trained nurses may be approved for the payment of a grant if they are undertaking a course of two years' duration, together with six months' training in a hospital, and are seeking the certificate of the Central Midwifery Board. The position of existing health visitors ought, it is stated, to be fully safeguarded, but it is hoped that these will take steps to obtain the new certificate, and will receive encouragement and assistance in this endeavour from their local authorities. The Minister of Health announces that he is prepared to approve the payment by local authorities of the reasonable expenses incurred by health visitors in attending whole-time "refresher" courses lasting from two to four weeks, and designed to afford additional practical and theoretical knowledge. It is hoped that such courses will be organized in London and other large centres. Grants will be payable at a rate not exceeding £15 for each duly qualified student who has completed the six months' course, and at the rate of £20 for each year of training for those who have completed the longer course.

## Correspondence.

### LIME JUICE AND LEMON JUICE FOR PREVENTION OF SCURVY.

SIR,—In the old days of sailing ships with voyages of long duration the danger of scurvy was much greater than it is now; little was generally known of the etiology of the disease, and catering difficulties were much more marked. Dr. Lind and Sir Gilbert Blane, the pioneers of naval hygiene, were both very active in studying this scourge of the navy and endeavouring to eradicate it. Fresh fruit, lemon or orange juice, with vegetables as prophylactic and curative agents for scurvy, had been used by the Dutch as far back as 1564, and had been successfully employed by Sir Robert Hawkins in 1600; but their use had been more or less forgotten until Dr. Lind insisted on their value. His *Treatise on Scurvy* was published in 1754. In 1757 Lind's friend Mr. Ives, the surgeon to the squadron, induced Admiral Watson to provide the ships in the East Indies with an ample supply of lemon juice. Lind, however, recommended preserved juice on long voyages. The fresh juice was concentrated by heat to a thick syrup; as this was done in glazed earthenware vessels soluble lead salts were found, and Lind drew attention to this danger as "death in the pot." Trotter strongly opposed the use of this form of preserved juice, as it was said to undergo fermentation and become mouldy. It was Gilbert Blane's teaching and powerful influence which brought Lind's recommendation into use, for in 1786, when Blane was one of the Commissioners of the Navy Board, the use of lemon juice was ordered as an essential part of the naval dietary; this quickly resulted in the practical disappearance of scurvy from the service fleet. In 1782 two-thirds of an ounce of lemon juice a man a day protected the whole ship's company of H.M.S. *Suffolk* during a voyage of twenty-three weeks without touching port. In a discussion on the probable cause of this disease, which he attributed to "the lack of a certain element which is necessary for growth and repair," Blane foreshadowed the present deficiency theory.

From that time to the present so-called lime juice has been a standing ration, but its efficacy has disappeared. The reason for this has been ably shown by Mrs. Alice Henderson Smith. As originally prepared the lime juice was made from sweet limes (*Citrus medica*), with lemons imported chiefly from Spain. In 1793 war stopped these supplies, but in 1802 delivery was resumed, and scurvy, which had obtained a temporary hold, was again almost eliminated. About 1860, by the development of the cultivation of limes in the West Indies, a large quantity was made available, and the contracts entered into for the navy caused these, the sour lime (*Citrus medica*, var. *acida*), to supersede the sweet limes and lemons formerly in use, and for a time this new lime juice was believed to be better than the old. In Ross's polar expedition the original lemon juice had been used, but Sir G. Nares in 1875 was provided with the new West Indian lime juice. The former escaped scurvy, the latter suffered severely, thus demonstrating the failure of the new preparation as a prophylactic. The sister ship in the latter expedition, the *Investigator*, was supplied with lemon juice, and for twenty-seven months after leaving home she had few cases of scurvy, though the crew suffered great hardships.

The clinical evidence is clear that lemon juice is far more effective than lime juice in preventing scurvy, and this has been fully confirmed by a large number of laboratory experiments, carried out at the Lister Institute, at Greenwich, and elsewhere, which have determined the exact relative values. Recent history has shown that during the war scurvy was prevalent in Mesopotamia, Serbia, Russia, and Eastern Europe, and much has been written on the subject. In the Persian Gulf naval crews frequently develop a form of scurvy which is cured by issue of fresh fruit.

Recognizing that the necessary antiscorbutic could not be supplied by the preserved lime juice from West Indian sources as at present made, I endeavoured to provide an efficient, portable, and palatable substitute for the use of special ships and for such expeditions as those for polar

exploration. The experiments were carried out at Greenwich on guinea-pigs, which are extremely susceptible to the disease. Lemon juice was evaporated at room temperature *in vacuo*, and then made into tablets with sugar of milk. Each tablet contained the equivalent of half a lemon, and was protective even after a year's storage.<sup>1</sup>

Dried orange juice, which has practically the same antiscorbutic value as lemon juice, has been largely employed by Givens and McCluggage, who found that it retained its protective power for a considerable time, but in these preparations a certain amount of heat is used, which diminishes the efficiency of the product. Zilva, of the Lister Institute, found that when evaporated down and kept anaerobically the antiscorbutic properties are retained for a long while. The use of concentrated lemon or orange juice has thus been found effective in animals, and we may with confidence apply its use to man under conditions of service which preclude the regular provision of fresh fruit and other well known preventive substances. For general service, when large quantities are required, the unheated concentrated syrup, as obtained before being mixed with lactose, might be kept in bottles, and the equivalent of 24 c.cm. of fresh lemon juice be given to each man, after solution in water to which sugar has been added at the time of issue. This acid viscid syrup keeps well, as moulds will not grow on it—an important fact to note. The Admiralty are fully aware that the lime juice is a non-effective scorbutic, and it is only issued as an agreeable beverage; but nothing else is at present supplied as an antiscorbutic.—I am, etc.,

London, S.E.3, Feb. 15th.

P. W. BASSETT-SMITH.

### THE RURAL PRACTITIONER AND MATERNITY.

SIR,—It appears from a letter by Dr. T. H. C. Stevenson in your issue of January 24th (p. 191) that he has suggested that there was an increase in puerperal sepsis during four years after the war, owing to more women being attended in their confinements by medical men.

Perhaps my own experience in an average practice during those years may throw some light on the question. In the first place, I totally disbelieve that more women were attended by doctors than previously; quite the other way round—during the war years there was plenty of money, and in consequence more were attended by medical men. However, what is certain is that during those years there was an extensive prevalence of virulent influenza. In two cases full-time women died directly from bronchopneumonia—one died undelivered, and the other a few days after delivery. Five pregnant women died from influenzal pneumonia, all of whom miscarried before death, in each case the symptoms becoming hopeless in about twenty-four hours after delivery. On several occasions I have had difficulty, when called in by a midwife, in deciding whether the pneumonia was due to sepsis or to influenza. Many cases of influenzal pneumonia must have been certified as puerperal fever. I knew one case where a woman was cured by a specialist and was afterwards found to be suffering from pleurisy, which cleared up after the fluid had been drawn off.

In my practice there was an epidemic of puerperal sepsis in the cases of a midwife—a clean and good nurse—and I hesitate to say how many of her cases I attended and how many died. Not only so, but in some cases she attended for a neighbouring practitioner and the same result was observed. This medical man tells me that she never examined in some of the cases, the fatal infection being apparently conveyed by the infection of the diapers—droplet infection, I presume. The one thing certain about the source was the fact that she had contracted ozaena, perhaps after influenza. In many midwifery books an epidemic in the practice of a medical man in New York, of a similar nature, is quoted. Is it not time that salicylic acid absorbent wool should be used for diapers, or some similar antiseptic material?

The practice of midwifery has improved amongst the rank and file of the profession, as it has in the hospitals: then

<sup>1</sup> See Report War Section, Royal Society of Medicine, 1920, vol. xiii, pp. 51-69, read May 10th, 1920.

why this bitterness? We use forceps much less frequently, although our patients occasionally still bully us into applying them before they are theoretically required. Pituitrin saves many forceps cases, and is a most valuable improvement, if not altogether without risk. Scopolamine and morphine soothes many a hysterical patient over a long and painful first stage; like forceps, if used wholesale, it would, in my opinion, slightly raise the death rate; none the less it is an improvement we should not care to be without, and invaluable in its place. We use gloves instead of the naked hand; we use anal examinations to finish up after a careful abdominal palpation, and only examine per vaginam when in doubt or when interference is required; we examine the pelvis of our patients carefully at the sixth or seventh month, and if necessary induce labour four weeks before the date of the confinement. The progress is immense, and will continue: bitter criticism is uncalled for. We lag behind the specialist a little, as is unavoidable, but not so much as formerly. Of course, the specialist sees our mistakes and not our successes. Twenty-three years ago, whilst doing locumtenent work up and down the country, I was impressed with the skill of the general practitioner, and I am sure that the general improvement since then is immeasurable.

Pre-natal clinics and all similar institutions should be staffed by the general practitioners of the neighbourhood, and the specialist used for consultation or supervision; otherwise much valuable clinical material is perforce stolen from the most deserving branch of the profession. In the same way, cottage hospitals should be established in every parish, so that the necessary facilities for the practice of modern medicine might be within the reach of all. Work-house hospitals and all other hospitals, with the exception of the big teaching hospitals, should similarly be thrown open to the general practitioners of the neighbourhood. This is particularly important in the case of the junior practitioner waiting for his practice to grow; not so important, perhaps, in the case of the elderly man, who has already gained his experience and built up his practice.

In conclusion, I would say that any medical man who is called out to midwives' cases, and sees again and again women dying and beyond help for the lack of more skilled knowledge promptly applied, must know that every woman requires the assistance of a fully qualified medical practitioner at her confinement. This is so, not only in cases of haemorrhage, adherent placenta, concealed haemorrhage, placenta praevia, face presentations, transverse and breech, twins, and so on, but because we are an unhealthy and unnaturally living generation, full of all sorts of ailments that render us liable to sudden death in the most unexpected manner. As the perfect is not always obtainable (and sometimes, perhaps, not even desirable: faunticism is rife, and is itself a danger), he should see her at least before delivery and should be available quickly when required. It is unnecessary to enumerate all the medical and surgical complications that render this so desirable.—I am, etc.,

Wallasey, Jan. 25th.

F. WILLIAM INMAN.

#### CANCER IN AFRICAN NATIVES.

SIR,—Dr. J. Bell Walker has kindly sent me Dr. Charles F. Harford's remarks in the *BRITISH MEDICAL JOURNAL* of November 8th, 1924 (p. 884). These, and Dr. Leitch's that he quotes, diverge from my points. My cases of malignant disease (*BRITISH MEDICAL JOURNAL*, 1924, vol. ii, p. 689) were all living the old primitive native life, with years varying between famine and plenty. I take it that in every case there is an abnormal local factor; in sarcoma, perhaps, a blow had concentrated the unconscious mind on the spot. In carcinoma everybody admits the local irritant. Increased introspection would be favourable in a native. Why should an animal need an intellect to favour abnormal unconscious action? Perhaps the law of correlation has a bearing on the causation. We need the practical help of the psycho-analyst. As in the case of delusions and obsessions, a special sector of the unconscious mind is probably at work. In a case of bad suggestion in a human being the conscious and unconscious minds would both be specially directed to an unhealthy spot in their

system. I ren-on the causation, therefore, as follows: (1) a local, chronic, unhealthy irritation; (2) concentration of the unconscious mind on the spot; (3) this sector transmitting its vital action—electric or whatever it is proved to be—thus being responsible for the malignant cell change at the site. Let hospitals and experts come to the rescue.

May I mention the following example, as the result of environment governed by the law of correlation, in my view? I have seen very many reedbucks in Nyasaland (natural colour a brownish-grey), but, omitting albinism and one instance of a light rufous colour, I know of three cases of a silver-coloured reedbuck, and those from one place only. I think one each were shot by Major Grogan and Mr. de Fries, and one by myself (now mounted). Other parts, normally dark, remained so. Antelope at the place in question, could often be seen grazing amongst native cattle. It was an open grassy place with a good many pools. In the wet season more shallow ones were formed. I submit that the silver-grey colour was developed *in utero* to match the bright sun-reflection on these waters, and render invisible at a distance.—I am, etc.,

Limbi, Nyasaland, Dec. 13th, 1924.

J. E. S. OLD.

#### MYELOID LEUKAEMIA ENDING AS LYMPHATIC LEUKAEMIA.

SIR,—The case recorded by Dr. Walter Broadbent under the above title (*BRITISH MEDICAL JOURNAL*, February 14th, 1925, p. 306) is more probably an instance of an acute myeloblastic termination, a recognized ending of chronic myeloid leukaemia. Before the output of myeloblasts takes place the number of leucocytes has usually fallen very low—for example, to 3,000 or 1,500 per c.mm.—and the occurrence suggests exhaustion of the bone marrow.

The initial number of leucocytes in Dr. Broadbent's case was high—892,000 per c.mm.—and x-ray treatment was continued until the figure fell to 11,600. When a reduction is taking place it often continues for some time after x-ray treatment is discontinued, and when the initial number is large, as in this case, it is advisable to stop the treatment when the count is between 30,000 and 50,000. Otherwise the liability to this sudden ending is considered to be increased.—I am, etc.,

London, W.1, Feb. 17th.

H. LETHBRIDGE TIDY.

#### REX v. BATEMAN.

SIR,—The public as well as members of the profession are to be heartily congratulated on the quashing of the sentence passed upon Bateman at a recent trial: the public, because the confidence placed in the doctors will be reinstated; and the profession, because members will feel it is, as it has always been, their duty to act courageously, with the skill they are capable of and the knowledge they possess, knowing full well their action will receive the support of right-minded men. Bateman is also to be congratulated because he has not been sacrificed in vain. His trial has awakened a sense of right and of justice in his professional brethren, which will amount in the course of time to far greater value than any compensation that could be given him.

The trial has in addition made us consider, Where do we stand? In this as in other trials for criminal negligence in the conduct of cases, it has hitherto been possible to find two camps of doctors—one for and the other against.

The facts elicited in these cases are alike for both sides; but there is always room for speculation on their interpretation. The final interpretation of all the facts brought out lies with the judge. As interpretation of technical facts is difficult, even to the man of special knowledge, experience, and skill, it would, it seems to me, be advantageous in the administration of justice if the judge were able to consult during the proceedings with someone capable of giving him real assistance in medical matters.

Is it not possible to arouse doctors to ask for the principle adopted in the Workmen's Compensation Act to be applied in such cases as *Rex v. Bateman*? If that were granted assessors for this purpose should be independent of external influence, also they would prove worse than useless. The presidents of the various medical corporations would be, I think, fitting persons to select an assessor in medicine,

in surgery, in obstetrics, or in the science of drugs, as the case may be.

No doubt it is a source of satisfaction that Bateman retains his professional position, and that his name will remain on the *Medical Register* and, if he so desires, on the roll of the panel of doctors under the National Insurance Act.—I am, etc.,

Cambridge, Feb. 16th.

JOSEPH GRIFFITHS.

#### PULMONARY TUBERCULOSIS TREATED BY SPAHLINGER'S SERUM.

SIR,—Most of the tuberculosis workers with whom I have discussed the value of Spahlinger's serum are sceptical of its value, for a variety of reasons, and the information given under the above heading in your issues of January 3rd and February 7th does not tend to dispel this feeling.

In the *JOURNAL* of January 3rd (p. 43) we are told that a case of pulmonary tuberculosis with such extensive disease and such grave symptoms that the condition of the patient was "wellnigh hopeless" was treated first with Spahlinger's serum in Geneva on August 1st, 1924, and that ten weeks later (that is, October 10th, 1924) the disease seemed to be "completely arrested." Like your correspondent of January 10th (Dr. J. M. Johnston), I marvelled at the radiograms and should have welcomed the information he suggested.

On February 7th (p. 277), however, you were able to publish a further report under the same title, showing that the man died on November 3rd, 1924, and a letter is published, in which M. Spahlinger is said to attribute the cause of death to "typical pneumonia."

Now "typical pneumonia" conveys the impression of acute lobar pneumonia of pneumococcal origin, and the inference from the whole letter would seem to me to be that death was not due in any way to pulmonary tuberculosis. This impression of mine may be wrong, but I should be glad to know what others think. The further information which you publish in the same article puts a different complexion on the affair. It is there shown that the case of pulmonary tuberculosis which was "arrested" on October 10th, 1924, had a copious pulmonary haemorrhage on October 25th, 1924, developed "pneumonia" on October 27th, and died on November 3rd, 1924.

Whether pneumococci were or were not found in the sputum at the last illness, no one can doubt reasonably that the cause of death was bronchopneumonia following pulmonary haemorrhage due to pulmonary tuberculosis; and it seems to me that when M. Spahlinger wrote as to the termination of the case he either was not in possession of all the facts or did not appreciate the need for a complete statement.—I am, etc.,

CECIL G. R. GOODWIN.

Newcastle-upon-Tyne Sanatorium, Barrasford,  
Northumberland, Feb. 8th.

#### CANCER OF THE OESOPHAGUS.

SIR,—Sir Charters Symonds (February 14th, p. 330), referring to Mr. Souttar's introduction of spiral wire intubation funnels in lieu of gum-elastic ones, restricts their use to those familiar with the oesophagoscope, and mentions that this will set a limit to their application—an opinion with which all will agree. On the other hand, he states that "the elastic tube can be introduced after a little experience, and has been used somewhat extensively by a number of surgeons." Again, that malignant obstruction of the lower end of the oesophagus can "usually be traversed by a condé bougie, or feeding tube when the straight variety cannot be passed"; and that "once such a tube can be passed and retained for three or four days, then the thin-walled rubber tube carrying the silver wire suggested by Dr. Hill can easily be inserted and worn indefinitely" (the italics are mine).

Surely Sir Charters Symonds does not advise—in these endoscopic days—the blind insertion of an intubation tube or a funnel in a malignant stricture of the oesophagus, in the haphazard way in which it has been used in the past?

So far as Dr. William Hill's intubation tube is concerned—and I have had considerable experience in its use—the

designer introduced it with the same restrictions as Sir Charters Symonds has placed on Mr. Souttar's tubes—namely, for perendoscopic use only, and for those skilled in endoscopic procedures.

It is admitted that the danger of perforation, especially in certain cases of tortuous cicatricial varieties of cancerous growths, is real, even in the hands of the most experienced endoscopists. Surely such a catastrophe is more likely to occur after the blind passage of a bougie or other appliance.—I am, etc.,

London, Feb. 16th.

IRWIN MOORE.

#### WHOLE-TIME MEDICAL OFFICERS.

SIR,—If Major Hefferman will do me the honour of re-reading my letter as a whole his alarm will be allayed. He will then see that the sentence which he quoted as indicating the policy of a particular hospital was merely the statement of a hypothetical case put forward during the course of an argument.

The reasons for the conclusion drawn in that sentence were set out in the two preceding paragraphs, and he will perhaps forgive me for thinking that as a scientific man he would have been better employed in a critical examination of those reasons than in turning over the pages of the *Medical Directory* in search of irrelevant material.—I am, etc.,

Sheffield, Feb. 14th.

A. E. NAISH.

#### ISOLATION HOSPITALS FOR SCARLET FEVER.

SIR,—*"Life is not designed,"* said Robert Louis Stevenson, "to minister to a man's vanity. . . . It is a friendly process of detachment. When the time comes that he should go, there need be few illusions left about himself. *Here lies one who meant well, tried a little, failed much—surely that may be his epitaph.*"

His word fits the broad tombstone of humanity, but it sits with peculiar felicity upon the graves of physicians. Life for them is a procession of disappointments aggravated by the circulars of credulous chemists. It is a poor day that brings no flattering promise, a bright night that has seen no disillusionment. They hope so much, persist so patiently, and achieve so little.

In the current *JOURNAL* Dr. H. Cameron Kidd's letter on isolation hospitals (February 14th, p. 332) drives home the point. Just two short weeks ago you recorded Dr. W. Robertson's tale of "a series of 200 consecutive cases of scarlet fever treated in their own homes in Leith, the largest proportion of which were working men's dwellings, and among which not a single instance of spread of infection took place"—a plea for the Milne method of treatment. Dr. Robertson is now M.O.H. for Edinburgh. One hoped that his word from such a city might carry the method into the therapeutic position it ought by right to occupy.

Instead comes a call for "more stately mansions" in the isolation camp. Thus the "friendly process of detachment" goes on. Yet after thirty years of general practice I recall, amid ventures, advances, failures, no measure in treatment which has so consistently fulfilled expectation. I do not say that scarlet fever handled thus is never fatal, never severe, never complicated; but I am convinced that by this method the majority of cases run a milder, safer course. And there is never any infection. That is certain. Isolation becomes unnecessary. General recognition of the fact would mean an immense economy to these islands.

Have isolation hospitals had so much credit from their scarlet fever patients that more money should be spent on them? Scientific precision is never within reach of the system. At the end of a dangerous and expensive seclusion the patient returns to society a potential risk to his fellow creatures. How real the risk is we learn too often. And always the scarlet fever hospital is itself a menace to the community—parents, friends, nurses even, spread infection from it. Doctors and staffs do their best, and these reflections are not directed at them. They are the victims of a system in which the dice are loaded against them—they do their best with no chance of kudos.

Sometimes the Milne method has been tried in these institutions. But principles and routine, the spirit of these

places and their great airy spaces, are dead against the test. You cannot deal faithfully with this thing by the perfunctory injunction of a few children in a draughty ward. Milne himself always gave "careful injunctions to avoid cold for three weeks and to have the children warmly clad." The method is simplicity itself. But unless its few plain directions have been followed to the letter, it is futile to criticize or condemn. On the Continent there is a growing interest in this method, and the exigencies of medical work under war conditions proved its value to more than one French observer.—I am, etc.,

Belfast, Feb. 15th.

ROBERT WATSON.

#### A JOURNALISTIC INDISCRETION.

SIR,—In view of the recent articles that have been appearing about 86, Brook Street, in the *Daily News*, I feel compelled to ask you to be good enough to publish this brief note, in which I would desire emphatically to dissociate both myself and any of my colleagues from the etiology of those articles.

I may just add that our united disapproval has found expression not only in an attempt on my part to suppress the publication of the last two articles, but also in a letter repudiating all knowledge and responsibility of them, written to the General Medical Council.—I am, etc.,

DRURY PENNINGTON,  
Medical Director.

86, Brook Street, W.1, Feb. 16th.

#### HISTORY OF HARLEY STREET.

SIR,—I am engaged upon a short history of the Harley Street and Wimpole Street district from a medical point of view, as that has, I believe, never been done before. I should be very grateful to any of my professional brethren for personal or topographical information relating to any of the houses in these or adjacent medical streets, including Cavendish Square.—I am, etc.,

26, Welbeck Street, W.1, Feb. 16th.

C. EDWARD WALLIS.

### Obituary.

#### E. E. KLEIN, M.D., F.R.S.,

Formerly Lecturer on Histology and Advanced Bacteriology,  
St. Bartholomew's Hospital Medical School.

DR. EDWARD EMANUEL KLEIN died at his residence in Hove on February 9th, in his 81st year. He was born on October 31st, 1844, at Ersee, near Vienna, the son of a Hungarian merchant, and received his medical education at Vienna. He devoted himself to microscopical anatomy, and before the age of 24 had published a monograph on the oesophageal musculature. In 1869 the New Sydenham Society decided to publish a translation of the *Manual of Human and Comparative Histology*, edited by Professor Stricker of Vienna, and Klein was sent by Stricker to London to make arrangements for this translation. Among those whom he met during this his first visit to England were Huxley, Burdon-Sanderson, and John Simon. He returned to Vienna in the autumn of the same year; but following a parliamentary subsidy of £2,000, voted to enable the medical department of the Local Government Board to undertake special investigations, Sir John Simon, medical officer to the Privy Council and afterwards general medical officer to the Local Government Board, invited Klein to return to England in April, 1871, in order to undertake certain researches of a kind for which he seemed peculiarly fitted.

Those who came in contact with him here recognized him as a brilliant young histologist, well trained in what was then a very brilliant school—Vienna. At that time the earliest work in this country on the particulate nature of contagion was being done by Sir John Burdon-Sanderson; but bacteriology was quite in its infancy. Klein was allotted quarters in the Brown Institute under Burdon-Sanderson, then its superintendent. His early papers are to be found in the Local Government Reports from 1871 onwards; they are essentially the work of a histologist, dealing with the microscopical morbid anatomy of such diseases as sheep-pox, typhoid fever, and scarlet fever. In particular he worked out the histology of the lymphatic

system, and in 1873 published a book on that subject which is justly regarded as a classic. This was followed two years later by another on the lymphatic system of the lungs.

He began bacteriology, after the manner of a histologist, by looking for the infecting agent with a microscope; then after a year or two he got on to cultural work. If Burdon-Sanderson be not so reckoned, Klein was the earliest bacteriologist in England. Burdon-Sanderson went off on physiology; Klein abandoned histology and stuck more and more to bacteriology. The sort of work he did may be judged from the succession of papers he poured out year by year in the Local Government Board Reports. He cannot, of course, be placed alongside Pasteur, who founded bacteriology, or Koch, who developed it as a working science. But Klein did great things for bacteriology in England. He made many mistakes, as we can see now, but he was a pioneer and kept himself and this country abreast of what was going on on the Continent. He did far more than any other man to develop the subject in England. In recognition of his pioneer investigations he was elected a Fellow of the Royal Society in 1875.

Klein had not long settled in London when the Medical School of St. Bartholomew's Hospital secured him as a lecturer on histology, though his broken English was at first a source of merriment to the ribald student. He held this post for many years, and subsequently lectured also on general physiology jointly with Dr. J. S. Edkins, until the latter took over the whole lectureship. In 1890 he opened a private school of bacteriology in Great Russell Street, taking pupils to train, of whom Sir Ronald Ross was one. Sir Frederick Andrewes and Sir William Hamer also worked there under him. A year or two later the Medical School authorities of St. Bartholomew's allotted him a laboratory at the top of the school buildings, where Sir Frederick Andrewes continued to work with him; and was joined later by Dr. Mervyn Gordon and Sir Alexander Houston. To these pupils and fellow workers Klein allotted particular pieces of investigation commissioned by the Local Government Board, for the practical distribution of the annual grant by the Board for research was usually left to him. He went on working in his laboratory at Bart's up to the time of his retirement.

In 1873 he had collaborated with Burdon-Sanderson, Michael Foster, and Lauder Brunton in the preparation of *A Handbook for the Physiological Laboratory*; his section on histology, though very useful to advanced workers, was rather over the head of the ordinary student. In 1879 he published jointly with the medical draughtsman, E. Noble Smith, an illustrated *Atlas of Histology*. In 1883 his well known *Elements of Histology* appeared; this proved very successful, and later editions were translated into French and German. In 1884 he published *Micro-organisms and Disease; an Introduction into the Study of Specific Micro-organisms*, which was considered to be one of the most important books from the point of view of the establishment of bacteriology as a science. In the eighties, in conjunction with Dr. Gibbs, he undertook an investigation of Asiatic cholera, and subsequently produced a form of prophylactic treatment for this disease. He was concerned with several important inquiries: thus, in 1876, he gave evidence before the Royal Commission on Viriscence; in 1893 he investigated the typhoid epidemic in Winchester and Southampton, and the scarlet fever outbreak in Glasgow; subsequently he turned his attention to the bacteriology of food decomposition. He continued his researches for the Government, retaining his appointment under the Local Government Board for about forty years in all. One of his more important investigations was in connexion with the cause of plague; his *Studies in the Bacteriology and Etiology of Oriental Plague* appeared in 1906. Indeed, some of Klein's best work was done late in life. In the course of his inquiries for the Fishmongers' Company he established standards for shellfish pollution, which still hold good. For some years he was an active member of the Scientific Grants Committee of the British Medical Association.

Dr. Klein married in 1877 Sophia Mawley; she died in 1919. He leaves a son, Dr. Bernard Klein, and a daughter. The funeral was on February 12th at Hove Cemetery.

**JAMES WATSON ALLAN, M.B., C.M.,**  
Late Physician Superintendent, City of Glasgow Fever Hospital.

DR. JAMES WATSON ALLAN of Broughton, Peeblesshire, who recently died, was educated at Glasgow, where he graduated M.B., C.M. in 1869. He was elected a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow in 1918. He spent several years of his early professional life as surgeon to the Belford Hospital at Fort William. At that time he took a very active interest in the geology and natural history of the surrounding country and erected a meteorological outfit in the hospital grounds. Dr. Allan later became physician superintendent to the Belvidere Fever Hospital of Glasgow, where he remained for many years. He was subsequently appointed physician and lecturer to the Royal Infirmary, and established a consulting practice. He was also for some time physician superintendent of the City of Glasgow Infirmary at Bellefield, from which he retired a year or two ago. Dr. Allan was chairman of the Glasgow Central Division of the British Medical Association from 1905 to 1907, and was a member of the Glasgow and West of Scotland Branch Council from 1900 to 1902. He was the author of several publications on infectious diseases and industrial medicine. He was a Fellow of the Society of Antiquaries.

A colleague writes: Dr. Allan was for many years physician superintendent of the City of Glasgow Fever Hospital, Belvidere, and as "Allan of Belvidere" was held in affectionate remembrance by a wide circle of former assistants. Few men can have exerted such a deep influence on his subordinates as he did by his example. He was a man of great sympathy, tact, and consideration for others; while he commanded respect by his wide professional knowledge and devotion to duty, he earned affection by his kindness, unselfishness, and unfeigned sympathetic interest in his subordinates. This interest followed them throughout their subsequent careers. He was a man of wide reading and extensive culture, to whom the saying *Nihil humanum a me alienum puto* was specially applicable. He was a member of the Glasgow Philosophical Society and a Fellow of the Archaeological Society (Scotland). He took an active part in the proceedings of local medical societies, and was at one time president of the Glasgow Southern Medical Society. Dr. Allan was unmarried. He was a brother-in-law of the late Sir William Macewen, who was a fellow student and contemporary at Glasgow University.

**EVAN JONES, M.R.C.S., L.S.A.,**  
Formerly of Aberdare.

THE news of the death of Dr. Evan Jones, formerly of Aberdare, has caused much sorrow in South Wales and will be received with great regret by many old members of the Council of the British Medical Association, who had learnt to respect his sound judgement and to admire his genial character. He was born in 1837 and received his medical education at St. Thomas's Hospital. He took the diplomas of M.R.C.S. and L.S.A. in 1858, and immediately afterwards went as assistant to Dr. Roberts at Aberdare, the centre of a large colliery district. He soon became extremely popular among the workmen, and continued to direct a very large practice in the Aberdare valley until, in 1909, he retired and took up residence in London, where he was often seen at medical dinners and other public functions.

He must have been one of the oldest members of the British Medical Association, for his name appears on the list for 1864—the earliest available. He was a member of the South Wales and Monmouthshire Branch Council for several periods, and became honorary treasurer in 1905; he was elected by the Branch to be its representative on the Central Council of the Association in 1887 and continued to serve until 1904. He was at one time a member of the Journal and Finance Committee. He was also, from 1894 to 1901, a member of the Parliamentary Bills Committee, which at that time did much of the work now conducted by the Medico-Political Committee. He held many appointments in the county of Glamorgan, was one of the oldest magistrates, and an income tax commissioner. He was an

ardent Freemason and was twice Master of the St. David's Lodge, Aberdare—first in 1873, and again, showing how well he was still remembered, in 1923. He joined the Volunteers early in life, rose to the rank of colonel in the Welsh Brigade, and received the V.D. The funeral, which took place at Treccynon, Aberdare, on February 13th, was of a private character.

DR. FRANK W. A. GODFREY of Scarborough died in a nursing home on February 3rd, aged 64. He was born at sea during the voyage of his parents to Australia, and he received his early education in that country. He subsequently studied at the University of Edinburgh, where he graduated M.B., C.M. with honours in 1883. After serving as resident surgeon to the Edinburgh Royal Infirmary and resident medical officer at the Edinburgh Royal Maternity Hospital, he went to Scarborough, and held the post of house-surgeon to the Scarborough Hospital and Dispensary. Later he joined Drs. John and Everley Taylor in partnership, and ultimately became head of the practice. He was appointed to the honorary medical staff of the Scarborough Hospital in 1892, and on his resignation in 1909 was appointed honorary consulting surgeon; he was also president of the hospital in 1917 and 1918. During the war he worked at the Scarborough Hospital. Dr. Godfrey was an ex-president of the York Medical Society, and was president of the Yorkshire Branch of the British Medical Association in 1909. He is survived by his widow and three daughters. Before the commencement of business at the Scarborough Police Court on February 4th the Mayor paid tribute to the memory of the late Dr. Godfrey, who, he said, was a man who did a very great deal of public service and would always be remembered as an ideal citizen.

DR. FREDERICK HENRY DE GRAVES BEST of Waltham Cross died on January 23rd, aged 55. He was educated at St. Bartholomew's Hospital Medical School, and took the diplomas of the Conjoint Board in England in 1895. Three years later he succeeded Dr. Rentzsch in practice at Waltham Cross, and subsequently became medical officer and public vaccinator for the Cheshunt District of the Edmonton Union. He was highly esteemed by his patients and all with whom he came in contact. He was a member of the East Hertfordshire Division of the British Medical Association. The funeral was attended by a number of friends and by representatives of various local bodies.

DR. HENRY G. DEANS of Edenfield died on January 23rd in North Wales, whither he had gone for the benefit of his health, aged 57. He was the son of the late Mr. George Deans, J.P., of Kintore, Aberdeenshire, and was educated at Aberdeen University, where he graduated M.A. in 1887, M.B., C.M. in 1890, and M.D. in 1912. He had practised at Edenfield for about thirty years and was held in high esteem by his patients. He was a member of the Bury Division of the British Medical Association. Dr. Deans was a keen golfer, and in 1923 was chosen to represent the Rosendale Golf Club in the final for the Bury Infirmary gold trophy in aid of the cot fund. He is survived by his widow.

Professor TRENDLENBURG, whose death on December 16th, 1924, in Berlin, was recently announced, was born in 1844. Part of his medical education was obtained in Edinburgh and Glasgow, where Allen Thomson, professor of anatomy, gave him special help and instruction. Having taken part in the wars of 1866 and 1870, Trendelenburg was appointed in 1874 director of the surgical department in the newly erected municipal hospital of Friedrichshain. In the following year he became a professor in the University of Rostock, and subsequently was appointed to the University of Bonn. In 1895 he joined the University of Leipzig, and became director of the surgical clinic. His pioneer work in joint surgery is well known, but he was

also renowned for his work on gastrostomy; he published also monographs on diphtheria and tracheotomy. The Trendelenburg position for operations on the bladder and other pelvic organs may be said to have put surgery of the pelvis on to a systematic basis. He was also responsible for some definite improvements in the treatment of varicose veins, and operations on the nose and face.

Dr. ARTHUR ERNEST HAYWARD of Truro died from pneumonia following influenza on January 27th, aged 62. He was the son of the Rev. G. A. Hayward of Colchester, was a student at St. George's Hospital Medical School, and took the diplomas of M.R.C.S. and L.S.A. in 1884. After a short period of work at Teignmouth and Brixham he went to Australia and practised at Southport near Brisbane, Queensland, and later at Hobart Town, Tasmania. He was honorary secretary and treasurer of the Tasmanian Branch of the British Medical Association in 1916-17, and on the offices being divided he served as treasurer of the Branch for 1918-21. On returning to England three or four years ago he settled at Truro, taking the practice of the late Dr. Aitken. He is survived by his widow and two daughters.

Professor ROBERT GERSUNG, a well known surgeon of Vienna, and one of Billroth's most distinguished pupils, has died at the age of 80.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

At a congregation held on February 14th the following medical degrees were conferred:

D.M.—W. R. Brain, G. J. D. Hodder.  
B.M.—J. L. Cox, T. H. Cathrall.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on February 7th the following medical degrees were conferred:

M.B., B.Chm.—E. A. B. Fritchard, B. Broadbent, R. Whittle, W. I. Daggett.  
B.Chm.—E. G. Morris.

### UNIVERSITY OF LONDON.

THE following have been recognized as teachers of the University in the subjects mentioned and at the institutions indicated:

St. Thomas's Hospital Medical School.—Dr. P. H. Mitchiner (anatomy)  
Mr. W. T. ...

D. McAlpine (neurology).  
of Medicine for Women.—Dr. ...  
University College Hospital Medical School.—Dr. Francis M. R. Walsho (oecology).

Lister Institute of Preventive Medicine.—Dr. R. Robison (biochemistry)  
The Royal Dental Hospital and London School of Dental Surgery is continued as a school of the University in the Faculty of Medicine (in dentistry only) for a period of one year from January 1st, 1925.

The date for the commencement of the M.B., B.S. examination has been changed from the fourth Monday in October to the second Monday in November.

The Ph.D. degree in science has been conferred upon Isaac Cohen and Dr. Edward C. Dodds, both of Middlesex Hospital.

Professor F. R. Fraser has been appointed External Examiner in Medicine for the year 1925.

The ceremony of Presentation Day will be held in the Royal Albert Hall on Wednesday, May 13th, at 3 p.m. A graduation dinner will be held at 8 o'clock on the same day in the Drapers' Hall, Throgmorton Street, E.C.

A course of lectures on mental deficiency for medical officers of local authorities and institutions and medical men engaged in work for defectives will be given at the central buildings of the University from May 18th to 23rd; the lectures will be supplemented by a course of clinical instruction.

A Carpenter Medal, together with a money prize, of the value of £20 in all, will be awarded in 1925 for a thesis of exceptional distinction in statistical, genetic, comparative, or experimental psychology, including the functions of the central nervous system and special senses, for which a doctor's degree (other than the Ph.D. degree) has been awarded during the three years ending May 31st, 1925. Applications to be sent in by June 10th to the Academic Registrar, from whom further particulars may be obtained.

Applications for grants from the Dixon Fund for assisting scientific investigations must be sent in by May 15th to the Academic Registrar.

Applications for grants from the Thomas Smythe Hughes Medical Research Fund for assisting original medical research must be sent in not earlier than May 1st and not later than June 15th, 1925. Particulars can be obtained on application to the Academic Registrar.

A University Studentship in Physiology, of the value of £50 for one year, and tenable in a physiological laboratory of the University or of a school thereof, will be awarded to a student qualified to undertake research in physiology. Applications must be received by the Principal Officer by June 1st, 1925.

### NATIONAL UNIVERSITY OF IRELAND.

THE Calendar for 1924 of the National University of Ireland contains an account of the establishment and constitution of the University, its regulations, constituent colleges, and various examinations. The names of the successful candidates in the examinations held in 1923 are published, and a list is supplied of the professors, lecturers, graduates, and diplomates of the University.

## MECHANICAL RESTRAINT OF LUNATICS.

A REGULATION, dated January 7th, 1925, has been made by the Board of Control under Section 40 of the Lunacy Act, 1890. This section deals with mechanical means of bodily restraint, and declares that this shall not be applied to any lunatic unless the restraint is necessary for medical and surgical treatment, or to prevent the lunatic from injuring himself or others. By the new regulation the Board determines that "mechanical means of bodily restraint" shall include all instruments and appliances whereby the free movements of the body or of any of the limbs of a lunatic are restrained or impeded, but that the following instruments and appliances only shall be used for such purposes:

I. A jacket or dress, made of strong linen or some other strong material (a) laced or buttoned down the back, having long outside sleeves fastened to the dress only at the shoulders, with closed ends to which tapes may be attached for tying behind the back when the arms have been folded across the chest; or (b) of some other pattern approved under the seal of the Board, a sample bearing the seal of the Board being in this case kept at the institution or workhouse for inspection.

II. Gloves without fingers, so fastened at the wrists that they cannot be removed by the wearer, and made of linen, leather (chamois or other), or some strong material, padded or otherwise.

III. Sheets or towels, when tied or fastened to the sides or ends of a bed or to other objects.

IV. If, in the opinion of the medical officer or medical practitioner who gives the certificate required by the section, some other mechanical means of bodily restraint is necessary in a particular case where the circumstances are exceptional, such means may be used with the previous sanction of the Board for such period as they may authorize.

During the use of any of these forms of restraint, except No. II, the patient must be visited frequently by a medical officer and be kept under continuous special supervision by an attendant. The following are not to be regarded as mechanical means of bodily restraint within the section, but are to be used only under medical order, and their use must be entered on the clinical records:

(a) The continuous bath. A cover shall not be used unless the aperture therein for the patient's head is large enough for his body to pass through.

(b) The dry and wet pack. No straps or ligatures of any kind shall be used, and the patient shall be released for necessary purposes at intervals not exceeding two hours.

(c) Splints, bandages, and other like appliances when used in accordance with recognized surgical practice for operations or the treatment of fractures or other local injuries, and not so as to interfere with the free movement of the body or limbs more than is necessarily incident to their use for such purpose.

(d) Gloves, if so fastened as to be removable by the wearer.

(e) Sheets or towels used only for the purpose of artificial feeding, and merely held, not tied or fastened.

(f) Trays or rails fastened to the front of chairs used by idiot children, cripples, or aged infirm adults to prevent their falling out and thereby injuring themselves, provided in the case of adults that it is within the patient's power to undo the fastening.

In framing this regulation, which defines the mechanical means which may alone be used, the Board has merely discharged the duty cast upon it by Subsection 6 of Section 40. It desires to guard itself most strictly against the supposition that it has thereby given any greater countenance to the employment of this form of treatment than it has hitherto shown. While recognizing the possible occurrence of cases in which its employment may be necessary and consistent with humanity, it remains of opinion that the application of mechanical restraint should always be restricted within the narrowest possible limits, that it should not be long continued without intermission, and that it should be dispensed with immediately it has effected the purpose for which it was employed. The regulation will come into operation on April 1st, 1925.

## Medical News.

A TELEGRAM from New York was published in the newspapers last week announcing that "a chemical compound which kills all germs in the kidneys and urinary tract" was being used with success at Johns Hopkins Hospital, Baltimore. It was said to have been discovered by Dr. Veador Leonard, working in co-operation with Professor Treat B. Johnson of Yale. The compound is stated to be hexylresorcinol. Mr. Frank Kidd has pointed out to us that Leonard published a full account of his researches in the *Journal of Urology*, December, 1924, and was careful to state that the drug seemed to act powerfully against Gram-positive cocci but to have an incomplete effect in the human being against the colon bacillus, except in very mild infections. Mr. Kidd adds that he has found that less than 10 per cent. of kidney infections are due to the coccal group of bacteria, the majority being due to the colon bacillus.

IN connexion with the arrangements recently entered into by the London School of Hygiene and Tropical Medicine with the Government of Southern Rhodesia for the development of research work in that country, the London School has appointed for a term of three years G. R. Ross, M.B., Ch.B., D.P.H., Ph.D., to be Rhodesian Research Fellow. Dr. Ross is at present lecturer in bacteriology in Leeds University. He will go to Salisbury, Southern Rhodesia, early in March, and will first study the etiology and pathology of blackwater fever. The laboratory at Salisbury has been placed by the Government of Southern Rhodesia at his disposal, and later investigations on lines from time to time to be agreed by Dr. Andrew Balfour, the Director of the School, in consultation with Dr. Andrew Fleming, the Medical Director, Southern Rhodesia.

THE Home Secretary issued on February 16th new regulations for workers exposed to the danger of silicosis. They will come into force on May 1st and apply to industries dealing with materials containing over 80 per cent. total silica. The Home Secretary is to appoint a medical board, and a company will be formed to collect funds from employers and distribute them to workers who have been awarded compensation by the board. Medical examinations of the workers are to be made at prescribed intervals, with a view to suspending from employment any found to be suffering from silicosis or tuberculosis. Workmen will also be examined when beginning such employment for the first time, in order that any with cardiac or pulmonary impairment may be excluded.

THE Fellowship of Medicine announces that Professor H. Maclean will lecture at the Royal Society of Medicine on March 20th, at 5.30 p.m., on renal disease, its diagnosis and treatment. On March 2nd also a three weeks' course in medicine, surgery, and gynaecology will commence at the Royal Waterloo Hospital, and, beginning on March 9th, the Central London Ophthalmic Hospital has arranged a four weeks' afternoon course. The Chelsea Hospital for Women and the Hospital for Diseases of the Chest (Brompton) have each arranged a two weeks' course to begin on March 16th. The last fortnight of March will be devoted to an intensive course arranged by the Royal Northern Hospital with the Royal Chest Hospital. The second week of the intensive course at the Prince of Wales's General Hospital, Tottenham, begins on February 23rd. An informal discussion on post-graduate study, open to all members of the medical profession in London as well as members of the Fellowship of Medicine from the provinces and overseas, will be held on March 18th, at 6 p.m., at the Royal Society of Medicine. Copies of the syllabus of each course may be obtained from the Secretary to the Fellowship at No. 1, Wimpole Street, W.1.

A COURSE of three lectures, on the history of influenza, diphtheria, and typhoid fever respectively, will be delivered by Dr. Charles Singer at University College Hospital Medical School on March 5th, 12th, and 19th. The lectures, which will be given at 4.15 p.m. on each day, are open to medical students of the University of London.

A MEETING of the Federation of Children's Rescue Committees will be held at the Kingsway Hall, Kingsway, W.C., on Friday, March 6th, at 5.15 p.m., when the Duchess of Atholl, D.B.E., M.P., will take the chair. The speakers include the Bishop of Kingston, Dr. A. H. Norris (Chief Inspector, Children's Branch, Home Office), and Dr. Elizabeth Sloan Chesser.

THE next meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health will be held on Friday, February 27th, at 5.30 p.m., at 1, Upper Montague Street, Russell Square, W.C. Mr. Somerville Hastings, F.R.C.S., will give a lecture, with lantern illustrations, on "Measures to prevent aural defects."

At the meeting of the Industrial Applications Section of the Royal Microscopical Society on Wednesday next, at 20, Hanover Square, Dr. James A. Murray will at 7.30 p.m. begin the first of a series of three lecture demonstrations on the making of microscopical preparations. The first lecture will deal with wet preparations. The first lecture

THE jubilee of the Metropolitan (Queen's) Nursing Association for Nursing the Poor in their own Homes will be celebrated by a service in St. Martin's-in-the-Fields at 2.15 p.m. on March 18th.

THE trustees of the Ella Sachs Plotz Foundation for the Advancement of the Scientific Investigation announce that applications for grants to be held during 1925-26 should be in the hands of the executive committee before May 15th. If all the funds are not assigned in the spring, further consideration will be given to applications received before September 15th. Such applications should be sent to the secretary of the executive committee, Dr. F. W. Peabody, Boston City Hospital, Boston, Massachusetts, U.S.A., from whom further information may be obtained. Researches will be favoured that are directed towards the solution of problems in medicine and surgery, or in branches of science bearing on apparatus and supplies needed for special investigations. Thirty-two applications were received during last year, and grants were made in eight instances—six in the United States, one in France, and one in Switzerland.

THE metropolitan borough council of Bermondsey has adopted a scheme of health propaganda. The programme covers a wide range, including questions of preventable and other diseases, housing, personal hygiene, food, and industrial diseases, and the propaganda is to be undertaken by leaflets, advertisements, electric signs, town-hall lectures, open-air demonstrations, and the establishment of a central office of information. There are indications that the enterprise of Bermondsey may stimulate other bodies, including the London County Council, to similar efforts.

THE King has granted permission to Dr. A. J. Ornstein to wear the Cross of Chevalier de l'Ordre de la Couronne conferred upon him by the King of the Belgians in recognition of valuable services rendered in combating malaria in the Katanga province of the Belgian Congo.

THE half-yearly election for the admission of fatherless children to the Royal Infant Orphanage, Wanstead, E.11, will be held in May next. Children are received from birth up to 7 years of age and maintained and educated until 16. Application should be made as early as possible to the secretary at the orphanage.

THE University of Bari, in Southern Apulia, which was inaugurated on January 15th, possesses a medical faculty with chairs in clinical medicine, clinical surgery, gynaecology, and obstetrics, ophthalmology, hygiene, medical anatomy, and pharmacology and therapeutics.

THE late Dr. Herbert Williamson, physician accoucheur to St. Bartholomew's Hospital, who left estate of the gross value of £62,932, with net personally £61,336, bequeathed £1,000 to the endowment fund of St. Bartholomew's Hospital Medical College.

THE issue of the *Paris Médical* for February 7th is devoted to physiotherapy. Professor Regaud contributes an account of the physiological basis of radiotherapy of malignant growths, and A. Lacassagne reviews the present position of radio-active substances in internal medicine. J. Lavedan discusses the cardio-vascular reactions due to x rays, and R. Proust and R. Coliez consider the possibility of improving the penetration of x rays and radium emanations.

THE widow of the late Dr. Paul Delbeuf, whose death we announced in our issue of January 31st (p. 246), has offered an annual prize of 1,000 francs to be awarded by the Société de Chirurgie for the best work on a gynaecological subject. The typescript should be sent to the general secretary, M. Barbarin, Avenue du Président Wilson, Paris, before March 1st.

AN Italian League against sexual dangers has recently been formed under the presidency of Professor Ettore Levi. Two courses in tropical medicine and medical parasitology will be held during the year at the Hamburg Institute for Marine and Tropical Hygiene. The first will take place from March 9th to May 16th, and the second from October 2nd to December 12th. Further information can be obtained from the Institut für Schiffs- und Tropen-Hygiene, Bernhardstrasse 74, Hamburg 4.

AN institute for the study of occupational diseases has been founded at Leningrad under Government auspices. The new institute for the study of criminal psychology in Paris is to be named after Lombroso. THE Minister of Health has appointed Mr. Howell E. James to be secretary of the Welsh Board of Health.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *BRITISH MEDICAL JOURNAL* alone unless the contrary be stated. Authors desiring reprints of their articles published in the *BRITISH MEDICAL JOURNAL* are requested to communicate with the Financial Secretary and Business Manager, 423, Strand, W.C.2, on receipt of proof.

ALL communications with reference to advertisements as well as orders for copies of the *JOURNAL* should be addressed to the Financial Secretary and Business Manager, 423, Strand, London, W.C.2. Attention to this request will avoid delay. Communications with reference to editorial business should be addressed to the Editor, *BRITISH MEDICAL JOURNAL*, 423, Strand, W.C.2. Communications intended for the current issue should be posted so as to arrive by the first post on Monday or at latest be received not later than Tuesday morning.

The telephone number of the *BRITISH MEDICAL ASSOCIATION* and *BRITISH MEDICAL JOURNAL* is Gerrard 2630 (Internal Exchange). The telegraphic addresses are:

EDITOR of the *BRITISH MEDICAL JOURNAL*, *Antiology Westrand*, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westrand*, London.

MEDICAL SECRETARY, *Mediscera Westrand*, London.

The address of the Irish Office of the *British Medical Association* is 16, South Frederick Street, Dublin (telegrams: *Barillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### SNORING.

DR. SAMUEL SAMUEL (Leeds) writes: In reply to "Wiltshire," the snoring is probably due to the patient recently acquiring, owing to some state of health, the habit of sleeping on his back. If the patient will make an effort to resume sleeping on his side the "flapping" of the soft palate causing the snoring will cease.

#### INCOME TAX.

##### Assistant's Expenditure.

"A. G." who qualified in 1922, acted during the year ended April 5th, 1924, as a temporary assistant, then as a ship surgeon, and afterwards as a locum tenens. During 1924 he had been holding an appointment as an assistant. Can he deduct any of the following expenses: (1) Agents' fees, (2) travelling expenses, (3) purchase of necessary instruments, (4) cost of sea kit (ship's uniform, etc.)?

\*. The governing principle is that expenses must be incurred wholly, exclusively, and necessarily in the performance of the duties of the office. Applying this rule as judicially interpreted: (1) Agents' fees are incurred prior to the performance of the duties and strictly are not allowable; we believe, however, that they are often allowed in the case of locum tenens, on the ground that the person doing such work is not so much holding a succession of appointments as exercising his profession in a particular way. The position as to (2)—travelling expenses—is the same as in the case of agents' fees. (3) Expenditure on the purchase of instruments is allowable only in respect of sums spent on their replacement and maintenance—the cost of acquiring or improving the equipment is capital outlay. (4) The cost of the sea kit would not be allowable.

### LETTERS, NOTES, ETC.

#### A DISCLAIMER.

THE EDITOR OF THE "LANCET" (423, Strand) writes: As communications have reached this office suggesting that a compliment paid to the *Lancet* recently in a Sunday newspaper was inspired by some member of the staff, will you let me assure your readers that this was not the case, and that the views expressed are not ours.

#### INUNCTION TREATMENT OF SCARLET FEVER.

DR. JOHN BROWN writes: A letter issued by Dr. W. Roberts referred to in the *JOURNAL* of Jan. 10, 1925, I can support by many years' experience. I used pure carbolic oil, which was given freely in all cases of scarlet fever. The results were excellent and fully justified the Milne method of treatment. I published a paper on the prophylactic advantages of early and continued inunction of carbolic oil in scarlet fever in the *BRITISH MEDICAL JOURNAL*, 1887. Moreover, I am confident that scarlet fever should not be treated in hospitals if this can be avoided. The disease tends to be more severe when so many are in one hospital. With plenty of fresh air and isolation in the home, with inunction, results are more favourable. Burning a little brimstone on hot cinders in the sick room should be done.

#### TREATMENT OF DIABETES INSIPIDUS.

DR. T. FIELDING WOODHEAD (Studdersfield) reports the successful treatment of a very stubborn case of diabetes insipidus occurring in a man aged 45, and attributed to alcoholic excess. The extreme thirst was most difficult to control; mineral waters were prohibited, and cold milk was found to be the best thirst quencher. Whenever the patient was thirsty he was allowed to drink one-half of a breakfast cup of cold milk, and was instructed to sip the remainder. With proper self-control in this respect the thirst soon disappeared. As the patient was very exhausted at first, one teaspoonful of whisky in milk was allowed three times a day, until the specific gravity of the urine rose to 1010. Mr. Woodhead believes to be the best stimulant. All hot milk Dr. Woodhead believes to be the most essential part of the treatment. White meat, such as fowl, pork, and fish, and also eggs, were allowed; sugar was given, and a bitter tonic was found very valuable in reducing the craving for alcohol. The urine was examined twice a week until the specific gravity increased to 1010, after which weekly examinations were sufficient. One incident during the treatment convinced Dr. Woodhead that it was on correct lines. When the urine specific gravity had reached 1010 the patient felt much better, and gravity had reached 1010 the patient felt much better, and though a change of air would be beneficial, so, without obtaining consent, he went to a hydropathic establishment where the diet was not restricted. Within a week his condition had deteriorated to its previous level and the specific gravity of the urine dropped to 1003. Resumption of treatment, however, gave complete relief.

#### AN OPTICAL PUZZLE.

DR. HORATIO MATTHEWS (London, W.) writes: No one has seen a straight line; everything we see suggesting straightness would, if continued, be manifestly curved and even arched or bowed. The accompanying diagram explains why this is so. As long as the arrow-head progresses, even though it be in a divergent direction, the angle A B C diminishes (where B C is a line of vision). Consequently there must come a position when, the angle being zero, the arrow-head is seen immediately in front of the observer. Thereafter the angle will once more begin to increase, and the arrow-head will commence to traverse across the middle line to the opposite side of the field of vision. In nature such a line would be one drawn from a star on the left, the field of vision to a star on the right, but optically it describes a curve across the vault of the sky. The same principle applies to any so-called straight line in the field of vision. So long as its direction moves round the retina, so long will the retina move it round.

#### MOTOR TAXATION AND REGISTRATION.

THE Automobile Association has issued a pamphlet setting out for motorists in simple language the various requirements of the law on taxation and registration. It explains what to do when changing its character, or when licence and obtain its unexpired value. It also contains tables showing at a glance for any period of the year the exact amount of tax payable for annual, quarterly, or shorter period licences. Copies will be sent to motorists on receipt of a postcard addressed to the Secretary, Automobile Association, Faun House, New Coventry Street, W.1.

#### "HYGIENE JINGLES."

DR. R. C. EVERITT ATKINSON, Commissioner of Public Health in Western Australia, has published a small book entitled *Hygiene Jingles* (Hospital Electrical and Radium, Ltd., Adelaide), with lyrics in sound principles. The author's intention in his preface is as follows: "in a sentence in his preface, tragically of elegantly of a rubbishy bin, tragically of a mosquito, feelingly of a fly, or sympathetically of your 'inside,' and see how really difficult it is." His success may be judged perhaps by the following stanza:

A girl who's nice  
May once or twice  
Have ulits or leo  
Within her hair,  
But self respect  
Will soon detect  
And then eject  
Them from their lair.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 37, 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 40 and 41. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 67.

## An Address

ON

## SOME ASPECTS OF CHOLELITHIASIS.

DELIVERED BEFORE THE LISTERIAN SOCIETY, KING'S COLLEGE HOSPITAL, ON JANUARY 21ST, 1925,

BY

SIR BERKELEY MOYNIHAN, Bt., K.C.M.G.,  
M.S. LOND., F.R.C.S.

SENIOR SURGEON, LEEDS GENERAL INFIRMARY.

THE surgery of cholelithiasis has two objects: it is concerned primarily with the health or the rescue of the individual patient; it is now concerned also with an attempt to discover the causes of the condition, so that its prevention may, in some degree at least, become possible. Research, no less than therapy, is an aim of all the methods of surgery.

In an investigation of cases of cholelithiasis the conclusion has been reached that two factors are of chief importance in respect of causation: infection, and an increase in the cholesterol content of the blood.

Infection may be derived from any source—from the teeth; from the facial sinuses; from any part of the alimentary canal; from the urinary system; from other foci within, or without, the abdomen. Theoretically there is no infection which cannot, when uncontrolled, gain access to the blood and so find its way to any part of the body. The infections so arising find their way to the gall bladder by several routes. If they are alimentary in origin they may ascend from the duodenum along the common duct; they may reach the liver, through the portal circulation, and thence descend with the bile. They may be borne by the blood, or by the lymph stream; or may attack the gall bladder by direct invasion from a neighbouring organ. The immediate effect produced upon the gall bladder varies in different instances. If contaminated bile is the direct source of the infection the mucosa is first attacked, and the inflammatory changes pass outwards through all the walls of the gall bladder. If the disease is blood-borne, little clumps of organisms are first seen in the submucosa, and a crowd of leucocytes surrounds them. The inflammatory process thence extends inwards to the mucosa and perhaps outwards to the peritoneum. The infection of the gall bladder found in typhoid fever seems to start with great frequency in this fashion. If the invasion occurs through the lymph stream or by direct contiguity, the serosa is first infiltrated by organisms, which make their way slowly inwards towards the mucosa. Sections made of the gall bladder have demonstrated quite clearly these several paths of infection. In cases of multiple gall stones infection is invariably present in the gall-bladder wall. The view has been expressed that infection is the consequence, and not one of the chief causes, of the development of calculi. Such evidence as I have been able to gather seems to indicate quite indisputably that infection always precedes the deposit of stones. Indeed, our search now inclines to the recognition of infection in the gall bladder during the period before the stones are formed. The most frequent agent of infection in the gall bladder is the *Bacillus coli*. It is found in all stages of cholelithiasis, from the earliest to the most advanced. Table I shows this unmistakably. In many cases of cholelithiasis a history of other forms of *B. coli* infection, especially of the urinary tract, may often be elicited. Women are afflicted with gall stones at least twice as often as men. They are apt to suffer from bacilluria; and in the periods of pregnancy pyelitis or cystitis of *B. coli* origin is no uncommon event. There would appear to be a connexion between the infections of the urinary tract and those of the gall bladder. Walton in particular has emphasized the truth of this observation.

The infection which sets going a process of calculus formation must be mild and is often recurrent: it waxes and wanes. If it is severe an acute cholecystitis develops, and gangrene or perforation may occur. As this acute infection subsides it may leave a crippled gall bladder incapable alike of secreting or of discharging its contents; and stasis

TABLE I.—RESULTS IN 100 CONJECTIVE CASES FROM WHICH CULTURES OF THE GALL BLADDER WALL WERE GROWN.

A.—Showing the Relation between Degree of Lesion and Type of Infection.

	Streptococci	B. coli	Double Infection	B. proteus	Other Infection: B. lactis, Staphylococcus, Pneumococcus
Early lesion	5	19	1	1	14
At acute	1	7	2	—	5
Subacute cholecystitis	2	14	2	1	9
Chronic cholecystitis	—	2	—	—	2
Empyema of gall bladder	—	1	—	—	4
Total percentage	8	45	5	2	33

B.—Showing the Organisms found on Histological Examination of the same Cases.

	In Mucosa	In Peritoneum	All 4 rough	Total
Streptococcus	4	6	—	10
Pneumococcus, etc.	17	15	3	35
B. coli	20	25	5	50
B. proteus	1	—	—	2

and a milder sepsis may then together lead to the growth of stones. If the infection is mild there appear to be pauses in the growth and activity of the organisms, for after cholecystectomy the bile may be found sterile, and the walls of the gall bladder, though crowded with organisms, may show only an attenuated growth, or even none, on culture. The incidence, the abeyance, and the recurrence of infection are shown by the existence of several generations of stones in the gall bladder, each generation having stones of the same size—larger if of older date, smaller if more recent. Three generations are often found.

When infection, from whatever source derived, reaches the cavity of the gall bladder, where an excess of mucus is quickly secreted and produces stagnation, the process of calculus formation may begin. An examination by a rare of the gall bladder after removal shows that, as a rule, the smaller the stone the larger the proportion of cholesterol that it contains—the smaller stones, that is, are almost translucent. As they grow larger calcium begins to be deposited upon a spot here and there; the area covered increases, and finally the complete closure of a cholesterol nucleus in a calcium capsule may be seen. In other instances the calcium seems to infiltrate the stone, swelling in towards the centre. In still others the nucleus of the stone is a dark spot of calcium and cholesterol is deposited around it. The calcium is no doubt derived in part from the mucus secreted in excess and in part from the inflammatory fluids poured into the gall bladder when the infection has aroused a great response. We do not at present know why in one case cholesterol is the chief constituent of gall stones, and why in another calcium is the component. The connexion between a preponderance of cholesterol in the stones and a high cholesterol content of the blood is clearly suggested by our experience to be presently mentioned, and calcium is doubtless an evidence of a subdued, though persistent, local infection, and perhaps, too, an evidence of a deranged calcium metabolism of which in this connexion I know nothing. The infective origin of multiple gall stones can hardly be disputed; and the aphorism I ventured to express many years ago, that "a gall stone is a tombstone erected to the memory of the stones within it," remains true. These buried organisms are not always dead. I have found typhoid organisms viable twenty-eight years after the occurrence of typhoid fever; and Finney relates a case in which living typhoid organisms were found in the centre of gall stones thirty-five years after an attack of enteric fever.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Financial Secretary and Business Manager, 429, Strand, W.C.2, on receipt of proof.

ALL communications with reference to advertisements as well as orders for copies of the JOURNAL should be addressed to the Financial Secretary and Business Manager, 429, Strand, London, W.C.2. Attention to this request will avoid delay. Communications with reference to editorial business should be addressed to the Editor, BRITISH MEDICAL JOURNAL, 429, Strand, W.C.2.

Communications intended for the current issue should be posted so as to arrive by the first post on Monday or at latest be received not later than Tuesday morning.

The telephone number of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is Gerrard 2630 (Internal Exchange). The telegraphic addresses are:

EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology Westrand, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London.

MEDICAL SECRETARY, Medicisera Westrand, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### SNORING.

DR. SAMUEL SAMUEL (Leeds) writes: In reply to "Wiltshire," the snoring is probably due to the patient recently acquiring, owing to some state of health, the habit of sleeping on his back. If the patient will make an effort to resume sleeping on his side the "flapping" of the soft palate causing the snoring will cease.

#### INCOME TAX.

##### Assistant's Expenditure.

"A. G.," who qualified in 1922, acted during the year ended April 5th, 1924, as a temporary assistant, then as a ship surgeon, and afterwards as a locumtenent. During 1924 he had been holding an appointment as an assistant. Can he deduct any of the following expenses: (1) Agents' fees, (2) travelling expenses, (3) purchase of necessary instruments, (4) cost of sea kit (ship's uniform, etc.)?

The governing principle is that expenses must be incurred wholly, exclusively, and necessarily in the performance of the duties of the office. Applying this rule as judicially interpreted: (1) Agents' fees are incurred prior to the performance of the duties and strictly are not allowable; we believe, however, that they are often allowed in the case of locumtenents, on the ground that the person doing such work is not so much holding a succession of appointments as exercising his profession in a particular way. The position as to (2)—travelling expenses—is the same as in the case of agents' fees. (3) Expenditure on the purchase of instruments is allowable only in respect of sums spent on their replacement and maintenance—the cost of acquiring or improving the equipment is capital outlay. (4) The cost of the sea kit would not be allowable.

### LETTERS, NOTES, ETC.

#### A DISCLAIMER.

THE EDITOR of the "LANCET" (423, Strand) writes: As communications have reached this office suggesting that a complimentary paid to the *Lancet* recently in a Sunday newspaper was inspired by some member of the staff, will you let me assure your readers that this was not the case, and that the views expressed are not ours.

#### INUNCTION TREATMENT OF SCARLET FEVER.

DR. JOHN BROWN (Blackpool) writes: The circular letter issued by Dr. W. Robertson, M.O.H. for Edinburgh, and referred to in the JOURNAL of January 31st (p. 323), is one that I can support by many years' experience as M.O.H. for the borough of Bacup. I used pure carbolic oil, which was given freely in all cases of scarlet fever. The results were excellent and fully justified the Milne method of treatment. I published a paper on the prophylactic advantages of early and continued inunction of carbolic oil in scarlet fever in the BRITISH MEDICAL JOURNAL, 1887. Moreover, I am confident that scarlet fever should not be treated in hospitals if this can be avoided. The disease tends to be more severe when so many are in one hospital. With plenty of fresh air and isolation in the home, with inunction, results are more favourable. Burning a little brimstone on hot cinders in the sick room should be done.

#### TREATMENT OF DIABETES INSIPIDUS.

DR. T. FIELDING WOODHEAD (Huddersfield) reports the successful treatment of a very stubborn case of diabetes insipidus occurring in a man aged 45, and attributed to alcoholic excess. The extreme thirst was most difficult to control: mineral water was prohibited, and cold milk was found to be the best thirst quencher. Whenever the patient was thirsty he was allowed to drink one-half of a breakfast cup of cold milk, and was instructed to sip the remainder. With proper self-control in this respect the thirst soon disappeared. As the patient was very exhausted at first, one teaspoonful of whisky in milk was allowed three times a day, until the specific gravity of the urine rose to 1010. Hot milk Dr. Woodhead believes to be the best stimulant. All red meat was prohibited; this he considers the most essential part of the treatment. White meat, such as fowl, pork, and fish also eggs, were allowed; sugar was given, and a bitter tonic was found very valuable in reducing the craving for alcohol. The urine was examined twice a week until the specific gravity increased to 1010, after which weekly examinations were sufficient. One incident during the treatment convinced Dr. Woodhead that it was on correct lines. When the urine specific gravity had reached 1010 the patient felt much better, and thought a change of air would be beneficial, so, without obtaining consent, he went to a hydropathic establishment where the diet was not restricted. Within a week his condition had deteriorated to its previous level and the specific gravity of the urine dropped to 1003. Resumption of treatment, however, gave complete relief.

#### AN OPTICAL PUZZLE.

DR. HORATIO MATTHEWS (London, W.) writes: No one has seen a straight line; everything we see suggesting straightness would be continued, be manifestly curved and even arched or bowed. Why this is so. As long as the line is in a divergent direction,

the angle of vision increases (where B C is a line of vision). Consequently there must come a position when, the angle being zero, the arrow-head is seen immediately in front of the observer. Thereafter the angle will once more begin to increase, and the arrow-head will commence to traverse across the middle line to the opposite side of the field of vision. In nature such a line would be one drawn from a star on the right of the field of vision to a star on the left. Theoretically it is a straight line, but optically it describes a curve across the dome of the sky. The same principle applies to any so-called straight line in the field of vision. So long as its direction moves round the retina, so long will the retina move it round.

#### MOTOR TAXATION AND REGISTRATION.

THE Automobile Association has issued a pamphlet setting out for motorists in simple language the various requirements of the law on taxation and registration of motor cars and motor cycles. It explains what to do when buying or selling a car, when changing its character, or when wishing to surrender a car licence and obtain its unexpired value. It also contains tables showing at a glance for any period of the year the exact amount of tax payable for annual, quarterly, or shorter period licences. Copies will be sent to motorists on receipt of a postcard addressed to the Secretary, Automobile Association, Panmure House, New Coventry Street, W.1.

#### "HYGIENE JINGLES."

DR. R. C. EVERITT ATKINSON, Commissioner of Public Health in Western Australia, has published a small book entitled *Hygiene Jingles* (Hospital Electrical and Radium, Ltd., Adelaide), with a view to instructing children in sound principles. The author's intentions are epitomized in a sentence in his preface as follows: "Try to write, in verse, elegantly of a rubbish bin, tragically of a mosquito, feelingly of a fly, or sympathetically of your 'inside,' and see how really difficult it is." His success may be judged perhaps by the following stanza:

A girl who's nice  
May once or twice  
Have nits or lice  
Within her hair.  
But self-respect  
Will soon detect  
And then eject  
Them from their lair.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 37, 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships and locumtenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 67.

## An Address

ON

## SOME ASPECTS OF CHOLELITHIASIS.

DELIVERED BEFORE THE LISTERIAN SOCIETY, KING'S COLLEGE HOSPITAL, ON JANUARY 21ST, 1925,

BY

SIR BERKELEY MOYNIHAN, Bt., K.C.M.G.,  
M.S.LOND., F.R.C.S.,

SENIOR SURGEON, LEEDS GENERAL INFIRMARY.

THE surgery of cholelithiasis has two objects: it is concerned primarily with the health or the rescue of the individual patient; it is now concerned also with an attempt to discover the causes of the condition, so that its prevention may, in some degree at least, become possible. Research, no less than therapy, is an aim of all the methods of surgery.

In an investigation of cases of cholelithiasis the conclusion has been reached that two factors are of chief importance in respect of causation: infection, and an increase in the cholesterol content of the blood.

Infection may be derived from any source—from the teeth; from the facial sinuses; from any part of the alimentary canal; from the urinary system; from other foci within, or without, the abdomen. Theoretically there is no infection which cannot, when uncontrolled, gain access to the blood and so find its way to any part of the body. The infections so arising find their way to the gall bladder by several routes. If they are alimentary in origin they may ascend from the duodenum along the common duct; they may reach the liver, through the portal circulation, and thence descend with the bile. They may be borne by the blood, or by the lymph stream; or may attack the gall bladder by direct invasion from a neighbouring organ. The immediate effect produced upon the gall bladder varies in different instances. If contaminated bile is the direct source of the infection the mucosa is first attacked, and the inflammatory changes pass outwards through all the walls of the gall bladder. If the disease is blood-borne, little clumps of organisms are first seen in the submucosa, and a crowd of leucocytes surrounds them. The inflammatory process thence extends inwards to the mucosa and perhaps outwards to the peritoneum. The infection of the gall bladder found in typhoid fever seems to start with great frequency in this fashion. If the invasion occurs through the lymph stream or by direct contiguity, the serosa is first infiltrated by organisms, which make their way slowly inwards towards the mucosa. Sections made of the gall bladder have demonstrated quite clearly these several paths of infection. In cases of multiple gall stones infection is invariably present in the gall-bladder wall. The view has been expressed that infection is the consequence, and not one of the chief causes, of the development of calculi. Such evidence as I have been able to gather seems to indicate quite indisputably that infection always precedes the deposit of stones. Indeed, our search now inclines to the recognition of infection in the gall bladder during the period before the stones are formed. The most frequent agent of infection in the gall bladder is the *Bacillus coli*. It is found in all stages of cholelithiasis, from the earliest to the most advanced. Table I shows this unmistakably. In many cases of cholelithiasis a history of other forms of *B. coli* infection, especially of the urinary tract, may often be elicited. Women are afflicted with gall stones at least twice as often as men. They are apt to suffer from bacilluria; and in the periods of pregnancy pyelitis or cystitis of *B. coli* origin is no uncommon event. There would appear to be a connexion between the infections of the urinary tract and those of the gall bladder. Walton in particular has emphasized the truth of this observation.

The infection which sets going a process of calculus formation must be mild and is often recurrent; it waxes and wanes. If it is severe an acute cholecystitis develops, and gangrene or perforation may occur. As this acute infection subsides it may leave a crippled gall bladder incapable alike of secreting or of discharging its contents; and stasis

and a milder sepsis may then together lead to the growth of stones. If the infection is mild there appear to be pauses in the growth and activity of the organisms, for after cholecystectomy the bile may be found sterile, and the walls of the gall bladder, though crowded with organisms, may show only an attenuated growth, or even none, on culture. The incidence, the abeyance, and the recurrence of infection are shown by the existence of several generations of stones in the gall bladder, each generation having stones of the same size—larger if of older date, smaller if more recent. Three generations are often found.

When infection, from whatever source derived, reaches the cavity of the gall bladder, where an excess of mucus is quickly secreted and produces stagnation, the process of calculus formation may begin. An examination by x rays of the gall bladder after removal shows that, as a rule, the smaller the stone the larger the proportion of cholesterolin that it contains—the smaller stones, that is, are almost translucent. As they grow larger calcium begins to be deposited upon a spot here and there; the area covered increases, and finally the complete closure of a cholesterolin nucleus in a calcium capsule may be seen. In other instances the calcium seems to infiltrate the stone, stealing in towards the centre. In still others the nucleus of the stone is a dark spot of calcium and cholesterolin is deposited around it. The calcium is no doubt derived in part from the mucus secreted in excess and in part from the inflammatory fluids poured into the gall bladder when the infection has aroused a great response. We do not at present know why in one case cholesterolin is the chief constituent of gall stones, and why in another calcium is the component. The connexion between a preponderance of cholesterolin in the stones and a high cholesterol content of the blood is clearly suggested by our experience to be presently mentioned, and calcium is doubtless an evidence of a subdued, though persistent, local infection, and perhaps, too, an evidence of a deranged calcium metabolism of which in this connexion I know nothing. The infective origin of multiple gall stones can hardly be disputed; and the aphorism I ventured to express many years ago, that "a gall stone is a tombstone erected to the memory of the stones within it," remains true. These buried organisms are not always dead. I have found typhoid organisms viable twenty-eight years after the occurrence of typhoid fever; and Finney relates a case in which living typhoid organisms were found in the centre of gall stones thirty-five years after an attack of enteric fever.

So far I have spoken of multiple gall stones. On occasion we find not many stones but one only. A solitary stone is composed of pure cholesterol; it is not caused by infection, though it may set infection going by becoming impacted once or oftener in the cystic duct. It causes no "inaugural" symptoms. No evidence of its existence is given until it suddenly becomes lodged in the pelvis of the gall bladder and occludes the cystic duct. This event rarely takes place until the stone is of the size of a nutmeg. The stone is irregular and warty on the surface, like beeswax in appearance, almost translucent; and on section shows a characteristic appearance of spokes radiating from the centre. When the stone is larger calcium may be deposited between these spreading lines, or upon the surface. The solitary cholesterol stone, then, is not caused by infection, but results from a condition of hypercholesterolaemia. The diagnosis of "solitary cholesterol stone" is easily made when one remembers that none of the prodromal symptoms of cholelithiasis are present. The first symptom is an agonizing attack of pain coming quite suddenly, seizing the right half of the abdomen, piercing through to the shoulder blade, spreading across the epigastrium, and producing infinite unrest, difficulty in deep breathing, sweating, and prostration, until, in an instant, relief comes. The stone is released as quickly as it was engaged. When such events are repeated infection in the gall bladder is a necessary consequence.

The question of the cholesterol content of the blood is one for close examination in all suspected cases of cholelithiasis. With the skilful help of Dr. Cecilia Shiskin 280 patients suffering from various abdominal diseases requiring operation have been examined (Table II). Of

these, 101 were cases of cholelithiasis. Cholesterol is a member of the important group of substances known as lipoids. It is an invariable constituent of all active cells of the body, both in its free form and in combination as ester.

In disease it may occur in abnormal amounts in various organs, tissue fluids, and calculi. It is present in the blood in very variable quantities. The normal amount may be stated as 0.160 per cent., and in older people as rather more than this. For purposes of classification (Fig. 1) we regard

Less than 0.133 per cent. as indicating hypocholesterolaemia.  
Between 0.133 and 0.160 per cent. as being normal.  
Between 0.160 and 0.192 per cent. as being high normal.  
Above 0.192 per cent. as indicating hypercholesterolaemia.

Hypercholesterolaemia is found in cases of arterio-sclerosis, chronic nephritis, diabetes, the later months of pregnancy, and in cholelithiasis.

Of 101 cases of cholelithiasis (proved by operation) 66.4 per cent were females. The average cholesterol value

FIG. 1.

was 0.217 per cent.; 65 per cent. of cases showed hypercholesterolaemia; 23 per cent. had high normal values; 11.5 per cent. had normal values; and 2 cases only showed hypocholesterolaemia—one patient was a man aged 76, the other suffered from an acute empyema of the gall bladder. In both a low value was therefore to be expected.

It is interesting to compare these figures with those obtained in cases of gastric and duodenal ulcer. Twenty-six cases of gastric ulcer were examined; the average cholesterol value was 0.167 per cent.; 27 per cent. of the cases showed hypocholesterolaemia; 50 per cent. gave normal values; and 23 per cent. hypercholesterolaemia. Forty-one cases of duodenal ulcer were examined; the average value was 0.149 per cent.; 36.6 per cent. of the cases showed hypocholesterolaemia; 51.2 per cent. gave normal values; and 12.2 per cent. showed hypercholesterolaemia; and in some of these arterio-sclerosis was noted.

The diagnostic significance of an increased cholesterol content of the blood is therefore important. Over 75 per cent. of patients in whom hypercholesterolaemia was found were suffering from cholelithiasis. The blood examined after operation shows that after all operations of magnitude there is a fall in the cholesterol content. This fall is followed slowly, as a rule, by a rise which may carry the content up to or beyond the normal. A condition of

hypercholesterolaemia may then persist unless measures are taken to reduce the accumulation of cholesterol. To this end a careful supervision of the dietary is necessary. I have followed Chaulffard in this matter, and I now give to all patients after operation the following chart.

#### DIETARY.

This régime seeks to achieve three objects: to avoid any digestive disturbance; to decrease, or at any rate not to increase, the cholesterol content of the blood; and to prevent intestinal infection which might give rise to infection of the biliary tract.

#### Forbidden.

Fat and eggs.

Stews and fried foods.

Sweetbreads and liver, goose, duck, kidneys, black pudding. Pork, game, high or spiced dishes, oily fish, soft roe, caviare.

Cooked butter.

Peas, cabbage, raw vegetables.

Strong cheeses.

(Sweets made with eggs may be taken.)

Avoid aerated waters, alcoholic beverages, beer, and liquors. Take alkaline drinks and a drink of hot water at the end of each meal.

Frequent small meals, rather than a few heavy meals, should be taken.

#### Admitted.

Skimmed milk.

Soups made with milk, vegetables, rice, semolina, tapioca.

White meats, lean meats, boiled, grilled, or roasted.

Salt-water fish, containing little fat or oil (for example, sole, whiting, turbot, brill), and river fish, provided they are fresh and not fried.

Cereals.

Potatoes, mashed or in their jackets, turnips, endives, spinach, artichokes, asparagus, vegetables in purées, rice, vermicelli and macaroni.

Mild cheeses.

Fruit—after three months.

The greater frequency of cholelithiasis in women may be in some measure due to their blood condition. Dr. Cecilia Shiskin has found that just preceding and during the first day or two of menstruation the cholesterol content is high (Fig. 2); and that during pregnancy this value steadily augments (Fig. 3) until in the ninth month it is approximately double the normal. Percent.

We did not derive much help in diagnosis from an examination of the stomach contents by the Rikhsuss method. Out of 77 cases we found complete achlorhydria in 17, hypochlorhydria in 3, a low normal in 14, a normal in 18, a high normal in 8, and hyperchlorhydria in 17. The "types," of course, were not significant. The only point here which needs comment

is that which concerns the rather large proportion of cases in which achlorhydria was present. In all these the administration of dilute hydrochloric acid after operation (50 drops in a tumblerful of water once or twice daily at meal times) is necessary. The rate of emptying the stomach in these cases was: rapid in 27; normal in 34; delayed in 16. The normal period for emptying after the test meal is from one and three-quarters to two and a half hours.

#### DIAGNOSIS.

The diagnosis of cholelithiasis does not, as a rule, present much difficulty, for the formation of stones in the gall bladder, and those attempts at migration which cause hepatic colic, are terminal events. Cholecystitis precedes

cholelithiasis in all cases except those in which the solitary cholesterol stone is present. Our endeavour should be to recognize the presence of the infected gall bladder before the stones have had time to form. The symptoms to which I drew special attention in 1908<sup>1</sup> as "inaugural" are amply sufficient to indicate the existence of cholecystitis. They are symptoms referred by the patient to the stomach. The complaints are of a fullness, weight, distension or oppression in the epigastrium, coming as a rule within half or three-quarters of an hour after meals, relieved by belching, and dismissed almost on the instant by vomiting. These sensations are elicited with remarkable constancy by certain articles of diet, especially those containing greasy or acid material. There is a sensation of tightness, which, if unrelieved, may become acutely painful; by it the patient is made restless, and from it he obtains relief by bending the body forwards, by flexing the right thigh on the abdomen, or by loosening all garments which press upon the waist. There is often a complaint of acidity or heartburn, and in the act of belching there may be bitter and acid regurgitation. Many patients notice that quite suddenly there may be a great gush of saliva into the mouth. While discomforts last there may be a "catch in the breath." When a deep forced breath is taken an acute stabbing pain may be felt on the right side, of such severity that the act of respiration is suddenly checked. Faintness, nausea, sweating of the face and neck, and a sense of great prostration may be followed by vomiting. There may be a slight sensation of chilliness and of shivering, especially in the evenings; "goose-flesh" is mentioned repeatedly in the clinical histories as a very disagreeable experience. Upon all these symptoms, which may exist for years, a series of attacks of colic may be imposed. Our efforts, however, should now be directed to the recognition of the precalculeous stage of the disease. Recently, with the very skilful co-operation of Dr. L. A. Rowden, this aspect of our work has received close attention.

The radiological evidence of a pathological gall bladder

FIG. 3.—Changes in cholesterol contents of blood with the progress of pregnancy. (After Shiskin.)

may be direct or indirect. There are times when stones are quite clearly seen in the x-ray photograph, and there are times when the gall bladder shows an opacity greater than that of the stones which lie within it, when what may be called a "negative shadow" is seen. The appearance of the shadows of stones is variable. When the stone consists chiefly of calcium the shadow is very opaque. When the stone is composed largely of cholesterol and a surface deposit only

of calcium is present a "new moon" shape, or a "wedding-ring" shape may be recognized in the shadow. Sometimes a mosaic pattern is found, and is due to the overlapping of shadows when stones are superimposed one on another.

The indirect effects produced by disease in the gall bladder are due either to pressure or to traction. A greatly enlarged gall bladder must make room for itself in the abdomen, and it does so by pushing aside the stomach or the duodenum or the colon. The outline of these displaced viscera, when they are filled with an opaque meal, is changed in greater or less degree from the normal. A "half-shadow" is seen in place of the usual shadow. When, on the other hand, the gall bladder after contracting attachments to these viscera begins to shrink it drags them away

and a conspicuous distortion in their shadows is then seen. A large pouch may form in the duodenum, or the colon be so hitched up to the gall bladder that no effort can displace its shadow.

It may be taken, I believe, as indisputable that a gall bladder which is clearly visible on ordinary radiological examination (apart, that is, from inflation of the peritoneal cavity) is pathological. The following table has been drawn up by Dr. Rowden.

TABLE III.—*Radiological Evidence of a Pathological or Calculous Gall Bladder.*

*Direct Evidence.*

1. Shadow of stones—
  - Opaque and solid;
  - "New moon" shape;
  - "Wedding-ring" shape;
  - "Mosaic" due to overlapping.
2. Shadow of gall bladder—
  - Every clearly visible gall bladder is pathological.

*Indirect Evidence.*

1. Pressure effects on—
  - (a) Duodenum;
  - (b) Pyloric part of stomach (half-shadows).
2. Traction effects—
  - (a) Pouching of duodenum;
  - (b) Displacements of duodenum;
  - (c) Displacements of colon;
  - (d) Fixity of duodenum or colon.

It is to be hoped that, by a combination of the several methods of inquiry I have mentioned—inquiry into the clinical history, into the cholesterol content of the blood, and into the radiologist's evidence—an accurate diagnosis of "pre-calculous" cholecystitis may become more frequently possible. When the knowledge gleaned from these sources is correlated with that gained by a chemical and bacterial examination of the gall bladder and its contents, then some clue as to the prevention of cholelithiasis may happily be discovered. I have now had the opportunity of removing a number of gall bladders in what I think may truthfully be called the "pre-calculous" stage; and a number of patients are being treated by large, intermittent doses of urotropine in the hope that they may be enabled to escape the attention of the surgeons.

When stones have formed in the gall bladder the morbid changes are generally extensive and well advanced. It is certain that the walls of the gall bladder are deeply infected, and the muscular layer destroyed; in many cases the infection has spread from the gall bladder to parts around, as is indicated by significant adhesions. Hepatitis in an early or advanced stage is often, though by no means always, present, and the pancreas is not seldom affected. In a large proportion of cases a condition of chronic appendicitis is found, and to all appearance is often of an older date than the disease in the gall bladder. In a small proportion of cases ulceration of the duodenum, or of the stomach, or of both, may be found also. The research work of the surgeon has shown the close affinity, the common causation, or the etiological relationship between these several diseases.

#### TREATMENT.

When the diagnosis of cholecystitis has been made, or the existence of stones within the gall bladder confidently asserted, the question as to the most appropriate treatment will arise. In the days to which we look forward with hope, and some expectation, it is possible that a recognition of earlier stages in the disease may enable us to prevent, or to delay, those advanced or terminal stages with which our therapeutic activities are now chiefly engaged. By the time that stones have developed, medical treatment can do nothing more than ensure a degree of clinical silence; it does not seem able to retard a steadily progressive pathological change. For the experience is not infrequent which shows that an inhibition of the symptoms of the disease, or more rarely their complete relief, may be witnessed, when in later days it is recognized that morbid processes have been steadily developing in the walls of the gall bladder; and perhaps cancer at last reveals itself.

The conditions which make it necessary to decide against surgical relief must be extremely few. I have often hesitated in days gone by as to whether the condition of a patient's heart would forbid the operation I was otherwise inclined to advise. But, under the tuition of Sir James Mckenzie, before he left Burnley, and after, I learnt that the removal of a diseased gall bladder was in many cases a sure method of giving relief to the heart. Glycosuria is often an effect of cholecystitis, and disappears after an operation which has not been too long delayed. Nephritis, too, need cause no anxiety if deliberate preparation for operation is made to extend over many days. The danger in the operative treatment of cholelithiasis comes from delay, which has led to infection of the ducts, and of the liver, to the "cholecystitic heart," and so forth. Yet the dangers of operation are very small. In the last ten years of my private work, including all cases—malignant cases, cases of stone in the ducts, in the ampulla, in every stage of activity—the gross mortality is 3.1 per cent. Hysterectomy, gastrectomy, colectomy, gastro-enterostomy, and splenectomy are included among the operations performed at the same time as the operation upon the gall bladder or bile ducts. In over half the number of cases the appendix was removed; in many it had been taken at an earlier operation. Some of the cases had been operated upon two, three, four, or more times before I saw them. The mortality is still too high; but it is almost certainly less than the mortality from cancer of the gall bladder alone, in cases not submitted to operation. There is, however, more than the death rate to consider. Operation is not only safer than continued medical treatment, it is also far more merciful. The agonies of hepatic colic are sometimes considerable; they are repeated on occasions which are perhaps very close together; they are sudden and unexpected in their incidence; and no sooner is one attack over than a dread of the next is felt. An operation for cholelithiasis is not always without pain, even when the nerves are blocked with quinine and urea; yet no patient will admit that the pain of the operation is equal to that experienced in one attack of colic. The surgery of cholelithiasis is difficult, sometimes extremely difficult. I held it to call for greater technical skill, and to present more problems for immediate accuracy of judgement, than any other branch of surgery; and the after-treatment too has its own grave problems.

If I might presume to offer any advice to the surgeon who has no great or continued opportunities for practical work, I would suggest to him never to do gastro-enterostomy in the absence of a demonstrable lesion which requires it; and to leave the surgery of the gall bladder alone. The fact that in my own work nearly one-quarter of the patients suffering from cholelithiasis have been operated upon before is an argument, not against the surgical treatment of the disease, but against an attempt by the inexperienced or untrained operator to deal with conditions which may tax all the energies and call out all the reserves of even the most proficient. Surgery is not only a craft, though craftsmanship of a high order is essential. It is a profession to which a man should feel not only complete devotion but also a sense of special dedication. Its practice requires the most flawless integrity in thought and act. It is not lightly to be undertaken by any who have not first surrendered to an iron discipline of training by the masters of their art. No one acquainted with the truth can deny that far too many operations nowadays are done by those who, having perhaps a measure of success in the trivial cases (none are trivial to a patient!), rashly embark upon procedures which they are not fully competent to undertake. And the good repute of surgery is wounded.

#### CHOLECYSTECTOMY.

In the surgical treatment of cholelithiasis when the stones lie only in the gall bladder, cholecystectomy has displaced cholecystostomy. I feel confident that this decision, which is almost universal, is sound and finds an ample warrant in the bacteriology and morbid anatomy of the gall bladder. The results of drainage of the gall bladder were often good, but they were bad in too large a proportion of cases: for

stones recurred, carcinoma sometimes developed, and the symptoms of an infected gall bladder persisted. Removal of the gall bladder was at first found difficult; the mortality was certainly a little higher, and the complications which ensued, due no doubt to lack of technical experience, were occasionally disastrous. But surgery is growing out of the indiscretions and the sins of its youth. Cholecystectomy rightly performed is as safe as drainage of the gall bladder, and the after-results are far more satisfactory.

The first problem is to decide, in the absence of gall stones, as to those appearances of the gall bladder which justify its removal. What are the signs of a diseased gall bladder? I should say that a gall bladder is infected when it has lost its normal blue colour, or its sheen; when it has lost its suppleness and its walls are thickened by fibrous tissue, or by the deposit of fat, especially along the lines of the vessels; when the cystic gland is definitely enlarged and changed in structure; when adhesions have been contracted to the parts around, especially to the duodenum, or the stomach; or when the cystic duct is thickened and the pelvis of the gall bladder has settled, in a mass of adhesions, firmly down upon the common duct.

In the operation of cholecystectomy there are dangers to be avoided, and there are points to be carefully remembered. The operation begins almost always at the cystic duct. I described this method twenty years ago, and was amused to hear it announced as a novelty, under the title of "retrogrado cholecystectomy," just before the war. In this operation, more, I think, than in any other abdominal operation, the exact position and relation of every structure that is encountered must be clearly defined. If the operation begins at the fundus blood trickles down on to the pedicle where the duct and vessels lie; they become stained and difficult to define clearly, and a rash blind clamping of the pedicle may result in almost irreparable disaster. The cystic duct is first clearly defined; it is almost always adherent to, and lies side-by-side with, the common hepatic duct before these join to form the common duct. When the duct is cleared it may be surrounded by a ligature and divided. It must not be cut flush with the common duct, but divided not less than an eighth of an inch away. If cut closer than this to the common duct it is possible that a stricture may form, and be the source of great difficulties. It is no uncommon thing for the cystic duct to be so tightened in elevating the gall bladder that the common duct is dragged upon and is made to look very like the cystic duct. I have operated upon not a few cases in which portions, sometimes even a length of  $1\frac{1}{2}$  in., had been cut out of the common duct. It is an elementary principle that the three ducts at their junction shall be clearly demonstrated. The cystic duct being divided, the cystic artery (there may be more than one) is ligatured, an aneurysm needle, or the cholecystectomy forceps, being first passed round it. I have not infrequently seen a broad forceps applied to the artery, which is then severed; this is a dangerous practice. To clamp ducts or vessels when the gall bladder is being forcibly elevated, and then to cut beyond the grip of the forceps, is a clumsy and perilous method of work. A ligature should be passed round every structure to be severed, and pains taken to make it indubitably certain that nothing but the duct or vessel is embraced. This no doubt sounds very elementary advice; but many patients would have been saved if only it had been understood and observed.

In my gall-bladder operations I was formerly much impressed by two events. Occasionally I would have a long struggle for the life of a patient, or even lose a patient, when I had expected an easy and untroubled convalescence. And occasionally I would find, on visiting a patient in the evening after the operation of cholecystectomy had been performed, that the dressings were saturated with bile. During operations I was struck by the irregular arrangement of vessels, and by the occasional discovery of an anomaly in the ducts. I therefore suggested to my colleague Mr. E. R. Flint that he should examine a series of bodies and endeavour to discover the variations—which were apparently not very infrequent—in the anatomy of the parts concerned in the operation of cholecystectomy. His work<sup>2</sup> has made matters plain. It is quite evident that

unless unremitting care is exercised it is easily possible to ligature the right hepatic artery instead of the cystic artery. A "cystic artery" that appears larger than normal, or has a "hump" in it, is often the right hepatic artery! Ligature of the right hepatic artery in a patient whose liver cells are already damaged as a result of an infection which is a part of his disease may be a serious or even fatal matter; and an accessory right hepatic duct is present in not less than 15 per cent. of cases. However watchful one may be, the wounding or the division of an accessory right hepatic duct may occur. If this should happen it is hardly worth while to repair the duct, or to anastomose its cut end with the divided cystic duct. But it is essential that a drainage tube should be left in the wound. I have closed the abdomen without drainage after removal of the gall bladder on many occasions; but I never do so now. A small tube does no harm: it leaves no gap in the abdominal wall if the rectus muscle is displaced outwards, and it gives a measure of safety obtainable in no other way.

Many of the patients who must submit to operation for cholelithiasis have been martyrs to their disease for long periods. Stones may have escaped into the common duct, or have passed upwards into the hepatic ducts, and biliary cirrhosis may have developed. The functional activity of the hepatic cells may be greatly impaired. A recognition of this truth must guide every stage in the care of the patient. In the day or two preceding operation as much glucose as possible should be given. During the operation the liver cell must not be made to suffer the burden which chloroform, a deadly drug, imposes upon it. The anaesthesia should, as far as possible, be induced and maintained by gas and oxygen. Hepatic insufficiency and acidosis are difficult conditions to master. Of the former we now recognize two types. There is one in which the amount of bile discharged ceases or is greatly reduced; jaundice deepens ominously; the mind becomes obtuse; vomiting develops; the pulse becomes slower, the patient more and more enfeebled; drowsiness precedes coma, and the blood urea steadily increases; renal failure, consecutive to hepatic failure, is then the cause of death. And there is another in which, after a normal course of from three to eight days, the bile discharged becomes copious, thin, and pale; jaundice does not change perceptibly; restlessness, great prostration, profound muscular weakness, and a peevish irritability are noticed; vomiting is present but is not as a rule severe; blood urea remains low; failure of the liver function is the cause of death.

Another menace, happily infrequent after operation upon the gall bladder or the ducts, is acidosis. Of this one seems to learn little from the textbooks on physiology; yet there are few conditions more necessary for the surgeon to understand.

#### Acidosis.

(A) Acidosis or ketosis is a condition in which certain acids gain access to the blood and therein threaten to diminish the alkali reserve in consequence of the very urgent necessity that they should be neutralized. The neutralization in the blood is effected chiefly by sodium bicarbonate. As this is accomplished the carbonic acid, whose ratio to  $\text{NaHCO}_3$  is constant, would be in excess but for the controlling mechanism which preserves the reaction of the blood at its normal level. Acidosis may therefore be considered as a condition brought about by the excessive withdrawal of bases in consequence of the formation of acids within the body. It is that state of metabolism of which the most

lucation in abnormal quantities of acid, lactic acid, and acetone). acidosis only the slightest alteration in the reaction of the blood is perceptible. The steady maintenance of the normal reaction depends on the presence of certain alkaline salts—the "buffer salts"—of which the chief is sodium bicarbonate,  $\text{NaHCO}_3$ .

For a stable blood reaction the ratio between the  $\text{CO}_2$  and the  $\text{NaHCO}_3$  is maintained at a constant value. When acids are added to the blood they react with the buffer salts, forming sodium salts of the respective acids, and these are excreted in the urine. If, therefore, large amounts of acids are continually poured into the blood, the buffer salts may decrease to a degree which renders it beyond the power of the body to replace them. Their concentration in the blood is therefore reduced below the normal, and the ratio between  $\text{CO}_2$  and  $\text{NaHCO}_3$ , being kept constant, and the carrying capacity of the blood for  $\text{CO}_2$  is also reduced, and accordingly  $\text{CO}_2$  may accumulate in the tissues. The blood under such conditions will, of course, cause stimulation of the respiratory centre; a more thorough ventilation of the lungs and of the

blood then results in an urgent attempt to prevent further accumulations of CO<sub>2</sub> in the tissues. This hyperpnœa is one of the clinical symptoms of acidosis.

(B) The acids which gain access to the blood are intermediate products in fat katabolism.

(C) The imperfect combustion of fats is associated with, and is perhaps due to the absence, or diminution, of, that product of carbohydrate metabolism which sets alight this combustion.

(D) A primary deficiency in carbohydrates is therefore an essential preliminary fault in cases of acidosis.

It may be due to an insufficient supply of food, such as occurs in cases of, say, pyloric stenosis, vomiting, or to an imperfect metabolism of carbohydrates of which there is no lack. The anaesthetic chloroform probably interferes with carbohydrate metabolism by its direct action upon the liver cell.

(F) In cases of carbohydrate deprivation the deficiency may be at once made good by the administration of glucose. This cannot be given in adequate quantities by the mouth to patients afflicted with acidosis, on account of the vomiting which is so persistent. If administered by the rectum its absorption, when considered in relation to the urgency of the patient's need, may appear slow. If it is given subcutaneously the quantity taken up is small, owing to the enfeebled systemic and lymphatic circulations. When administered intravenously there is no reasonable limit set to the amount which can be given. Either a 5 or a 10 per cent. solution may be injected; an isotonic solution contains 4.15 per cent. of glucose. Matas of New Orleans, a surgeon to whom our debt of gratitude is very heavy, was the first to suggest (in 1911) that glucose might be given by continuous instillation. He has recently<sup>3</sup> described an apparatus which renders easy the "continuous drip" intravenous administration of a glucose solution maintained at an equable temperature. About 8 pints may be introduced in the period of twenty-four hours; I have once introduced as much as 18 pints. A reaction is seen not infrequently—the patient shivers and then sweats, a miniature rigor occurring; no anxiety need be felt on this account. The cause of the reaction is doubtful; it may perhaps be the too rapid administration of the fluid.

(G) The mere accumulation of glucose within the blood is not, however, all that is necessary. The glucose must be utilized by the tissues. We owe to Thalimier of Milwaukee<sup>4</sup> the supremely important suggestion that this may be done by the injection of insulin.

My experience of the method is small, but it is enough to say that a new remedy of considerable importance is now at our disposal. Insulin must not be injected until there is a good store of glucose in the blood lest a hypoglycaemic reaction be caused; not less than 15 ounces of a 5 per cent. solution should have passed into the vein, and unless there is great urgency it is well to introduce an even larger amount, or to have a stronger solution. Lilian Farrar<sup>5</sup> has used a 20 per cent. solution for intravenous administration. As she points out, glucose is not only a food and source of energy, but also a stimulant to the tissue cells and to metabolism; the liver function is conserved by it and the glycogen store increased.

Fisher and Snell<sup>6</sup> record cases illustrating the value of the insulin treatment in pre-operative and post-operative non-diabetic acidosis.

Vomiting is often the warning symptom of impending acidosis. It is present along with great prostration and a considerable degree of air hunger, and with a sweet "new-mown hay" smell in the breath. The urine gives the characteristic reactions for acetone and diacetic acid.

Lavage of the stomach is the sovereign remedy for relief of the vomiting, which is most distressing. But in acidosis, as in cases of obstruction, or of adynamic distension of the stomach and duodenum, the lavage may need to be repeated so frequently as to be a tax upon the surgeon and a sore trial to the patient. Happily a most excellent method of lavage is made possible by the Jutte tube, or the Levin tube—tubes of about the same size as the Reliefs tube. If passed through the nostril they may remain for hours without distress to the patient, who may then drink fluids freely.

I have, I fear, wandered discursively over a large field in dealing with the subject of cholelithiasis. There are so many problems that confront us as we cope with this very formidable disorder that it is not easy to choose among them. There is so much still to learn. The relationship of the liver to the spleen, of both to the pancreas, and of all three to the reticulo-endothelial system, and the effect which injury to the liver cell has upon the kidneys, are matters calling for fullest inquiry. Though we seem to know so little of any of these organs, and still less of their interplay, the work of the surgeon which has so marvellously contributed to our clinical knowledge may still hope to prove not unworthy of regard as one of the most fertile of all methods of research.

CHALLIS PROFESSOR OF ANATOMY IN THE UNIVERSITY OF SYDNEY.

## LECTURE III.—PART II.

## THE PRACTICAL APPLICATIONS (continued).

## THE CONTROL OF TONE BY THE BRAIN.

## THE SELECTION OF PATIENTS FOR RAMISECTION.

I SHALL now consider the reflex arcs concerned in maintaining the two elements of tone, and the scientific principles for the selection of patients for ramisection.

Plastic tone is enhanced in degree in the decerebrate animal. It may appear as a component of postural contraction immediately after the mid-brain is cut across, so that, normally, prespinal pathways are employed by the impulses maintaining it. When decerebration is performed, plastic tone is increased in degree as a result of the release of this prespinal sympathetic reflex arc from higher levels of control. In addition to this, contractile tone is enhanced in value because of the release of a somatic prespinal reflex arc. In animals recently decerebrated this increase of contractile tone selects the antigravity muscles, and their antagonists are reflexly inhibited. The increase in plastic tone rigidly maintains the extended posture, which is endowed by contractile tone upon all four limbs of the quadruped, and maintains the condition of "reflex standing" for long periods of time. When the relaxation from the posture of extension occurs, plastic tone still remains, as is proved by the presence of "lengthening and shortening reactions."

The prespinal reflex arcs subserve the two components of tone of the normal skeletal muscle, and overactivity of these arcs accounts for the phenomena exhibited by the musculo in decerebrate rigidity. It was shown by Sherrington that cutting across the medulla oblongata led to flaccid paralysis of the limbs. More precisely, as Magnus has shown, the limits within which section of the brain stem produces decerebrate rigidity are as follows: The cranial limit is a plane passing dorsally at the level of the caudal limit of the superior colliculus and ventrally in the region immediately caudal to the mammillary bodies. The decerebrate rigidity persists until the level of entrance of the eighth nerve is passed. Obviously, therefore, the nuclei that constitute the cell stations of the prespinal reflexes responsible for decerebrate rigidity lie within these limits.

The work of Thiele in 1905, which is supported by the recent results of Bazett and Penfield,<sup>22</sup> indicates that the integrity of the lateral vestibular nucleus of Deiters is essential for the development of decerebrate rigidity. It may be concluded that this nucleus takes part in the completion of one of the reflex arcs, the hyperactivity of which is responsible for decerebrate rigidity. The vestibulo-spinal tract (Fig. 13), which lies in the region of the emerging motor root fibres of the spinal cord mainly on the same side as the nucleus from which it originates, constitutes the descending limb of the reflex arc.

The nucleus of Deiters is a special afferent somatic nucleus, and the reflex arc in which it is incorporated constitutes, therefore, the somatic prespinal reflex pathway. It subserves contractile tone, which has a selective incidence upon antigravity muscles maintaining the body erect.

The question arises whether the nerve cells incorporated in the sympathetic prespinal reflex arc can also be identified. The levels between which section of the brain stem produces decerebrate rigidity suggest that the formatio reticularis of the pons supplies the cell station of this arc. The reticulo-spinal tracts of the pons are anatomically of special

\* Delivered by Professor Elliot Smith at University College, February 2nd, 1925.

importance. Collier and Buzzard have termed them the ponto-spinal tracts. The anterior ponto-spinal tract, which is uncrossed, descends in the lateral zone of the medulla oblongata and the anterior funiculus of the spinal cord. The lateral ponto-spinal tract crosses to the opposite side and lies in the lateral zone of the medulla oblongata and in the lateral funiculus of the spinal cord.

Sherrington's experimental results are compatible with the view that the vestibulo-spinal and ponto-spinal tracts convey impulses to the spinal cord that are responsible for decerebrate rigidity. Section of the lateral half of the bulb abolishes the rigidity on the same side as the lesion. Section of one ventro-lateral column of the spinal cord in the cervical region destroys the rigidity in fore and hind limbs of the same side, while section of one lateral column in the upper lumbar region abolishes the rigidity in the hind limb of the same side as the section. The ascending limbs of these arcs are also in the antero-lateral funiculus: for section of the posterior funiculus does not abolish decerebrate rigidity.

In an experiment to study this point I have found that plastic tone does not disappear after removal of the nucleus of Deiters. First, decerebrate rigidity was produced by cutting across the mid-brain between the superior and inferior colliculi. Extensor rigidity developed rapidly and well. Now, in a phase of relaxation, when plastic tone was well shown in the right hind limb, I isolated the region of the lateral angle of the fourth ventricle on the right side by a crescentic incision, removing Deiters's nucleus and severing the vestibulo-spinal tract by this procedure. But the "lengthening and shortening reactions" were still exhibited. A second section at the junction of the pons and medulla was then made. The limbs became flaccid immediately. The "lengthening and shortening reactions" were no longer to be elicited. Obviously plastic tone depends upon a reflex arc that attains a level between the mesencephalon cranially and the medulla oblongata caudally. This is compatible with the view that the ponto-spinal tracts subserve the function of plastic tone.

It is possible for an incomplete lesion of the spinal cord to affect the pyramidal and concomitant descending tracts, so releasing the primary spinal arc from control, without affecting in any considerable measure the vestibulo-spinal and ponto-spinal tracts. Riddoch and Buzzard<sup>22</sup> have recently described cases of quadriplegia from high cervical lesions of the spinal cord, in which the distinctive qualities of decerebrate rigidity were reproduced. Riddoch reports that a tumour examination of one of these patients revealed a tumour in the region of the posterior and lateral columns of the fourth and fifth cervical segments of the spinal cord. The ventral portion of the cord was relatively little affected. It is clearly to be borne in mind that the extensor posture is a relatively unimportant character in establishing an analogy between the condition of spastic paralysis in man and decerebrate rigidity experimentally produced. The posture assumed is due to the selective incidence of contraction upon the skeletal musculature. Riddoch and Buzzard recorded that, in their patients, the position of flexion was sometimes encountered. On these occasions the flexors were more spastic than the extensors. This condition could sometimes be induced by holding the limbs in the flexed position for a short time. Further, McAlpino reported a case in which rigidity was not confined to extensor muscles, and flexor rigidity of the knee-joint was sometimes obtained.

Graham Brown has demonstrated beyond all doubt that plastic flexor tone may be exhibited in the limbs of the

monkey. These observations are of added significance in the light of Bazett and Penfield's work on chronic decerebrate rigidity. These authors describe two kinds of decerebrate rigidity—extensor and flexor. Their observations prove that the somatic reflex arcs producing contractile tone may selectively act upon either the extensor or flexor muscles. In extensor rigidity the reflex, of which the vestibulo-spinal tract is the descending limb, is involved. In flexor decerebrate rigidity the primary spinal reflex is, no doubt, responsible for the activity, for severe injury to the spinal medulla produces paraplegia in flexion. In both types of decerebrate rigidity plastic tone, which is enhanced in degree, and coexists with contractile tone, is maintained by the sympathetic prespinal reflex arc. In each case it is inhibited in the antagonists of the muscles exhibiting the rigidity.

Inhibition in the antagonists is not so complete in man as it is in the condition of acute decerebrate rigidity. Dr. Royle has called attention to this point. Riddoch mentions the fact that though the antagonistic muscles are relatively relaxed "they are certainly in stronger contraction than the corresponding muscles of a healthy individual."

I believe the explanation of this is that in an animal that has recently been decerebrated the extensor reflex arcs, chiefly through the nucleus of Deiters, immediately manifest increased activity. The isolated flexor spinal arcs regain activity only after a period of inaction of contractile tone on the extensors is not so complete, for the spinal arc endows this aspect of tone upon the flexors also. Reflex inhibition is now not complete. Bazett and Penfield's experiences with the chronic decerebrate animal support this view. Moreover, in patients suffering from spastic paralysis, plastic tone is not inhibited in antagonistic muscle groups; which accounts, in some measure, for resistance to active, reflex, or passive movement of the limb.

I have commented on the work of Bazett and Penfield to emphasize the fact that the posture of the patient is not the all-important criterion of rigidity. Even the flexed position may be due to a combination of both contractile and plastic tone which together cause rigidity in the sense in which this term is employed in this lecture. Contracture is employed in this category.

versely, the extensor position may be wholly due to contractile tone. Sympathetic ramification in such a case would be of no avail. Extensor fits usually fall into this category. This is beautifully illustrated in a case recently reported by Walshe,<sup>23</sup> in which two stages of the illness were observed. In the first stage the patient exhibited a condition of decerebrate rigidity. The limbs were extremely "plastic" and tended to remain for a considerable time in any position passively imposed upon them. The lower extremities were extended and adducted and the feet were semiflexed at the elbows, with the forearms pronated and the wrists and digits flexed. This attitude often replaces that of extension of the fore limbs of quadrupeds because the upper extremities are no longer "simple locomotor props." Passive movement revealed the presence of the "clasp-knife" character of the spasticity. The tendons-jerks exhibited tonic prolongation, and in some instances in response to repeated taps "step-ladder" shortening of the muscle was observed. In recording these features, Walshe established beyond doubt the identity of this condition with decerebrate rigidity experimentally produced.

In the second phase of the illness this condition was replaced by the progressive failure of reflex activity and deepening coma. In this stage tonic fits appeared as a con-

FIG. 13.—Diagram to indicate the part played by the vestibulo-spinal tract (arising from Deiters's nucleus) and the ponto-spinal tract (arising from the reticular nucleus of the pons) in the two reflex arcs concerned respectively with contractile and plastic tone.

comitant of cardiac and respiratory irregularities. In these fits the respiratory muscles were fixed and the limbs became so rigid in their customary posture that no tendon reflexes could be elicited. In severe fits of this kind the head retracted forcibly. At this stage none of the essential qualities of decerebrate rigidity, enumerated as characterizing the first phase of the illness, were exhibited, for plastic tone was not apparently enhanced in degree. The second phase was in all probability due to hyperexcitability of the somatic reflex pathways due to asphyxia or anaemia (cf. Walshe, Stewart and Pike, Warner and Ohnsted, Hunter and Royle). The fits are not comparable to decerebrate rigidity in which the enhanced tone is due to release in function of two prespinal reflex arcs—somatic and sympathetic. Yet the posturo displayed in each condition is the same. Taking into account the results of tests for the presence of plastic tone in addition to posture Walshe and Riddoch have been able to establish the essential identity of decerebrate rigidity and the condition of spastic paralysis, such as that which occurs in hemiplegia, quadriplegia, and the extended form of spastic paraplegia.

The only patients who can be expected to benefit from the operation of ramisection are those whose voluntary control of their muscles is intact, but whose movement is hampered by excessive plastic tone. By cutting the sympathetic nerves plastic tone is eliminated and the limbs freed from the spasticity. The presence of "lengthening and shortening reactions" is an indication for the operation of sympathetic ramisection for the relief of spastic paraplegia. Slowness in execution of the tendon reflexes is an important indication for the operation.

Conversely, rapidly executed reflex movements usually constitute a definite contraindication. The greater number of spinal injuries are accompanied by this type of reflex and plastic tone is at a minimum. This is due to the fact that a prespinal reflex is essential in higher forms for the maintenance of this property of muscle, and usually, though not always, as will be proved subsequently, this reflex is rendered inactive when the spinal cord is injured.

#### HIGHER LEVELS OF THE BRAIN CONTROLLING THE TONIC REFLEX ARCS.

Magnus has shown that in animals, such as the rabbit, cat, dog, and monkey, the whole of the cerebral hemispheres, including the corpora striata, may be removed and the tone of skeletal muscle remain of normal intensity. Nor is the tone altered when the brain stem is cut across behind the thalamus. Such a "mid-brain" animal, unlike the decerebrate preparation, is capable of a great variety of reflex activities—as walking, running, and jumping. It can right itself if overturned, the head at once resuming its normal posture. These are the "postural reflexes" of Magnus. Obviously, therefore, in these animals, the mid-brain provides an important part of the nervous mechanism utilized in the regulation of posture. It is when this region is taken away that release of the prespinal reflex arcs takes place to produce decerebrate rigidity. For instance, in higher forms, at least, as Magnus's observations upon the monkey reveal, the connexions of the visual pathway with the mid-brain play an important part in the nervous regulation of posture. Tecto-bulbar connexions therefore control the prespinal reflex arcs in these forms. Moreover, decerebrate rigidity develops after the removal of the red nuclei, and, as Walshe mentions, "it seems as though removal of the greater part of the red nucleus is an essential preliminary to the development of rigidity." In this process rubro-reticular fibres, which in man have attained special importance, are severed. The cells of the

substantia nigra are also known to send axones to the tegmental region of the brain stem.

In view of prevailing conceptions it is noteworthy that in the animals described by Magnus the postural reactions are carried out by the mid-brain in the absence of the corpus striatum. It would, however, be unwise to argue that in man the mid-brain structures exhibit this independence of the corpus striatum, for the principle of the shifting forward of function in the nervous system must not be lost to sight in this connexion. Moreover, it may well be that the physiological value of the corpus striatum is only adequately expressed in the presence of voluntary activity. In such a case the symptomatology of lesions of the corpus striatum, with the cerebral cortex intact, will be different from the experimental results of complete removal of both the cerebral cortex and corpus striatum.

For these reasons the observations of Magnus that "thalamus" and "mid-brain animals" exhibit tone of normal intensity and distribution cannot unreservedly be applied to man. It is possible that the corpus striatum in man, with the cortex intact, controls through the intermediation of subthalamic nuclei, as the substantia nigra, the sympathetic prespinal are subserving plastic tone. To study this point I have removed the corpus striatum on one side in birds, employing the domestic fowl and the sea-gull for this purpose. Birds represent a group widely divergent from mammals. In birds the corpus striatum has attained a relatively enormous importance, both structurally and functionally, and in certain respects its influence may present a closer analogy to that of man than is the case in most mammals. The operation is easily performed on birds because the corpus striatum constitutes, except for the septum and a small superficial area of cortex, the entire cerebral hemisphere. Further, in removing the corpus striatum, which is readily accessible because it forms the greater part of the surface of the hemisphere, the cerebral cortex may be lifted up and left in communication with the septum. In this way the tractus cortico-septo-mesencephalicus is left intact.

This operation produces rigidity of all the limbs. Standing is not evenly maintained owing to rigidity of the hind limbs. On this account in sea-gulls a tendency to rise on the toes is constantly exhibited and the bird does not maintain any given position for long. Birds in this condition often squat down, presumably to avoid balancing on the rigid limbs. The wings are also rigid, and here the nature of the rigidity may readily be studied. The wings are sometimes maintained in a position somewhat higher than usual, so that the adjacent borders are almost in contact with one another. The rigidity maintains its intensity during passive movement, and on account of its rigidity the wing remains fixed in the new position assumed. This occurs even though the position be so abnormal, as when the wing is folded over the mid-line of the back, that the fibrous structures contained within are put upon the stretch. Dependent positions are maintained equally well. Both wings exhibit this phenomenon after the unilateral operation, but the rigidity is greater on the same side as the injury. The rigidity is responsible for slowness of movement, especially on the same side. This is readily seen on watching the movements of the wing during attempted flight while the bird is held captive in the hand. A greater effort is necessary to carry the wing through a smaller range of upward movement than on the less affected side; increased effort marks downward movement also; and the wing seems to overshoot the position at which it normally

FIG. 14.—Diagram to represent in an entirely tentative way the influence of the cerebral cortex (acting via the corpus striatum, substantia nigra, and red nucleus) upon the activity of Deiters's and the reticular nuclei. Only those tracts which are mentioned in the text have been represented. The relays in the ascending spinal tracts have not been indicated.

ends. These alterations in the nature of the movement of the wings are greater on the side of the injury, so that the flight of such a bird, when released, is always in a circle, the bird tending to fly toward the more affected side.

This diffuse muscular rigidity is strongly reminiscent in an exaggerated form of the condition of the wing already described, in which, after the removal of contractile tone, plastic tone is accessible for independent study. I cannot avoid the deduction that increased plastic tone in both flexor and extensor muscles of the wing is responsible for the diffuse muscular rigidity which follows the removal of the corpus striatum in birds. This element of tone is so enormously increased that manifestations of the presence of the contractile component are in the background.

The condition of rigidity of the wing of birds above described is remarkably similar to Parkinsonian rigidity in man. Its diffuseness, resistance to stretching, and the tendency for fixation of the muscle at any length passively imposed upon it, are common to the two conditions; and in both conditions poverty and slowness of voluntary movement, which are probably due in part to the underlying phenomenon of rigidity, are notable concomitants.

Removal of the influence of the sympathetic innervation by section of the cervical sympathetic trunk caudal to the brachial plexus abolishes the rigidity of the wing. This property, like normal plastic tone, is subserved therefore by the sympathetic system. It is difficult to escape the conclusion that the basis of the rigidity following lesions of the corpus striatum is increased plastic tone, which is exhibited in all muscle groups, and that this is due to removal of control from the sympathetic prespinal reflex arc which maintains the plastic tone of normal skeletal muscle.

The different manifestations of excess of plastic tone in those cases of spastic paralysis which resemble experimental decerebrate rigidity, and in the condition of Parkinsonian rigidity, are capable of reconciliation. The fundamental difference between the two conditions is that, while plastic tone is increased in both, an excess of contractile tone is also exhibited in spastic paralysis, while it is not greatly in evidence in Parkinsonian rigidity. Contractile tone is selective in its incidence, and the plastic tone of the antagonists of the muscles selected by it is, to a very varying degree, reciprocally inhibited. In Parkinsonian rigidity this selective incidence upon muscles, and consequently the selective inhibition of plastic tone in the antagonists, are absent. In spastic paralysis resistance to passive movement is considerable till the position imposed upon the limb by contractile tone is overcome, when the resistance becomes less. A combination of contractile and plastic tone is responsible for the initial position in spastic paralysis. The posture assumed in Parkinsonian rigidity is due to plastic tone only exhibited in agonists and antagonists, and therefore resistance to passive movement is the same throughout the whole range of movement. The fact that postural reactions and intercurrent reflex movements are not exhibited in Parkinsonian rigidity as in spastic paralysis is a further indication that somatic activities, which include contractile tone, are in abeyance in this condition. The mechanism which inhibits plastic tone in order that a movement may be performed or to allow a new posture to be assumed is no longer active. This effect is probably the cause and not the result of the rigidity—that is to say, a predominant function of the corpus striatum is to regulate plastic tone. From a consideration of the other effects of corpus striatum lesions it seems that this regulation is especially in the interests of automatic and associated movements, and of emotional expression. These functions are no doubt impaired by the lesion; the rigidity itself may limit these activities still further.

It remains to be proved that the rigidity of paralysis agitans and allied conditions is subserved by a proprioceptive mechanism in order to establish completely the identity of the tendency in this condition to fixation of the muscle at any length imposed upon it, with the "lengthening and shortening reactions."

In the first place it must be borne in mind that the sympathetic reflex arc subserving plastic tone is not necessarily at the same level as the somatic connexions. There-

fore, in posterior root section, contractile tone may be affected without removing plastic tone.

Surgical operations upon the posterior nerve roots have necessarily been less complete than is possible under experimental conditions.

Leriche's cases, in which posterior root section was performed for the relief of paralysis agitans, are evidence of this. In one case the fifth, sixth, and eighth cervical posterior nerve roots were divided. In this case the rigidity was undiminished. Obviously, however, the sympathetic afferent connexions of the skeletal muscle of the limb were left intact by this operation because the posterior root of the first thoracic nerve was not attacked. Therefore this case does not disprove that rigidity is maintained by a proprioceptive mechanism. The first principle of posterior root section in man should be to include the posterior root of the first thoracic nerve in the case of the upper limbs, and of the first or second lumbar nerve in the operation for the lower extremities.

However, Walshe has recently brought forward strong evidence that the rigidity of paralysis agitans is due to the activity of a proprioceptive reflex mechanism. He has shown that injection of 1 per cent. novocain into the muscle at its motor point causes rigidity to disappear. While admitting the possibility that this effect may be due to direct action upon the muscle, he shows convincingly that the balance of evidence is in favour of the view that the afferent nerve terminations are affected.

Walshe's investigations upon the rigidity of paralysis agitans beautifully illustrate the fact that the tremor exhibited in this condition and the rigidity are subserved by two different nervous mechanisms. For although novocain abolishes rigidity the tremor is totally unaffected. The indications are that impulses through the cerebro-spinal tracts are involved in the production of spontaneous tremor, for it disappears after hemiplegia. This is in accord with the results of sympathetic ramisection in this condition. The rigidity is markedly diminished, voluntary power is increased, and movements are more ample and rapid, but the tremor is not appreciably affected when well established. But a patient with Parkinsonian rigidity without tremor, as for instance as a sequela of encephalitis lethargica, may derive sufficient benefit to justify the operation.

In a recent paper McAlpine<sup>22</sup> has described a patient who, as a sequela of epidemic encephalitis, developed Parkinsonian rigidity on the right side and a condition strongly resembling decerebrate rigidity on the left side. According to views advanced here, the diffuse muscular rigidity on one side was due to a generalized increase of plastic tone, lack of selective incidence being due to the absence of increase in contractile tone. The rigidity on the other side, however, was sometimes flexor and sometimes extensor. Therefore contractile tone was present and acted selectively on different groups of muscle at different times. Plastic tone was also enhanced in the upper and lower limbs of this side. It was exhibited by the presence of the "lengthening and shortening reactions." It was shown to the greater extent in the flexor and extensor muscles at any particular time according to the selective incidence of the contractile tone at the time. In the erect posture tone predominated in the extensor muscles of these limbs. Since the tone responsible for this decerebrate attitude consists of the two normal components of tone, the term "plastic tone" alone is clearly inadequate to describe the condition. Sherrington's term "postural tone" may be used for this purpose. Contractile tone reflexly imposes the position upon the body and plastic tone maintains this position once it is assumed. On passive movement the characteristic "lengthening and shortening reactions" indicating the presence of plastic tone are elicited.

In a natural attitude such as standing contractile tone is responsible for selective action upon the antigravity muscles and plastic tone fixes the length of the muscle fibres necessary to maintain this position. To accomplish voluntary movement from this position the prespinal reflex arcs responsible for postural tone must be controlled by the cerebral cortex. Evidence is accumulating that the cerebral cortex not only causes contraction of the appro-

prate muscle groups by way of the cerebro-spinal tracts, but inhibits the reflexes responsible for postural contraction. It effects this purpose through the intermediation of the cerebellum (Figs. 13 and 14).

An inhibitory pathway leads from the cerebral cortex to the anterior part of the superior vermis of the cerebellum through the medial part of the crus cerebri and the pontine fibres. Stimulation of the crus in a decerebrate cat leads to complete rigidity in the limbs of the same side and diminution of rigidity in those of the other side. Warner and Olmsted<sup>20</sup> have traced the origin of this inhibitory tract to the frontal region of the cerebral cortex. When the motor area was cut away no increase of extensor tone was observed on either side of the body. Definite rigidity developed at once in the opposite fore and hind limbs when the frontal area was removed. This observation is of great significance in view of the fact that, in man, pure cortical lesions of the pyramidal tracts do not produce spasticity. On the other hand, lesions of the area of the frontal lobe from which the fronto-pontine tracts originate (Campbell) are associated with a condition of "tonic innervation" expressed as inability to relax a contracted muscle group.

Warner and Olmsted have elucidated the course of this tract arising in the frontal region by studying the inhibition of rigidity obtained by electrical stimulation of the eut surface of the brain in various situations. They found that the inhibitory effect of the tract is bilateral, but predominantly on the crossed side. The tract passes from the frontal lobe through the medial part of the internal capsule. Below the level of the superior colliculi it crosses, in greater part at least, to the other side of the brain stem. It continues to the cerebellum by way of the middle cerebellar peduncle. The inhibitory tract is therefore fronto-ponto-cerebellar in its connexions. (See Figs. 13 and 14.)

Warner and Olmsted state that when this tract is stimulated a limb "becomes limp or rigidity goes 'limp and flaccid.'" They describe the effect of stimulation of the anterior surface of the cerebellar vermis as being "immediate and general relaxation of the rigidity." Obviously the inhibition affects both contractile and plastic components of tone which are enhanced in degree to produce decerebrate rigidity. The fronto-ponto-cerebellar tract, therefore, inhibits the effect produced by the somatic vestibulo-spinal and sympathetic ponto-spinal tracts. When this tract is ineffective the power to relax the muscles after being employed in muscular effort is defective. In the absence of a case purely of this nature in Dr. Royle's series it is interesting to note that the effect of sympathetic ramisection improves the power of relaxation of contracted muscles in spastic paralysis. It is to this fact that the increased control and rapidity of effecting voluntary movement are due. The patient need no longer inhibit plastic tone. His cortical control is mainly concentrated on executing movement.

It is worthy of note that tumours of the middle lobe of the cerebellum give rise to fits of a tonic character in which the extensor attitude of decerebrate rigidity is assumed (cf. Hughlings Jackson). Sherrington found that a rigidity somewhat similar to that ensuing on removal of the cerebral hemisphere set in after median section or ablation of the cerebellum. He was not convinced that the two conditions were identical. Thiele,<sup>21</sup> however, regarded the bilateral rigidity which followed removal or bisection of the vermis as being like decerebrate rigidity. He explained it as being due to loss of the inhibitory control of the vermis over the nucleus of Deiters. No doubt also the ponto-spinal tracts are released from control. It will readily be seen that the only effect of sympathetic ramisection upon tonic extensor pathway is to diminish the degree of rigidity during the extensor spasms. Since contractile tone remains practically unaffected after this operation the extensor attitude will still be assumed. This is another instance of posture alone not being an indication for ramisection.

The fact that the cerebral cortex employs the cerebellum as an intermediate organ through which it exerts an inhibitory influence over the postural reflex arcs of the brain stem is of great general significance. It confirms the

suggestion of Walshe that "the cerebellum is the organ through which the cerebral motor cortex influences postural activities and regulates posture in the interests of co-ordinated purposive movement." "It may be," he proceeds, "the subordinate mechanism employed by the cerebral cortex in the refined correlation of posture and movement." This view indicates that the cerebellum is employed by the cortex in the performance of active movements also. It reinforces postural tone in order to maintain the attitude of the body assumed during the performance of the movement initiated and executed by motor impulses which have their origin in the cerebral cortex.

In 1900, discussing the significance of the cerebello-cerebellar pathway which passes through the brachium pontis, Sherrington said: "Thus one and the same cerebral discharge may perhaps pour upon the motor root nerve cells a combination of cerebral and cerebellar impulses." It is on account of the influence of the cerebral cortex in the regulation of posture through the intermediation of the cerebellum that lesions of the cerebellar hemisphere cause inco-ordination of voluntary movements.

When a voluntary movement is completed cortical impulses reinforce contractile tone to determine the attitude assumed by the body. Plastic tone aids in maintaining this position because the muscle fibres exhibiting it are fixed at their new length. After sympathetic ramisection this necessary contribution is lost, but the influence of the cerebral cortex on contractile tone remains. In this connexion it is well known that tone is increased by attention. Dr. Royle has noticed that during the first period of re-education after sympathetic ramisection when the patient's attention is focused on the performance of a voluntary movement, under orders, the cortex greatly increases the amount of contractile tone exhibited in the limb. This increases the difficulty of the patient in performing the movement. On this account gently executed movements are far more effective than considerable effort in this stage of the re-education process.

Evidence is not wanting that plastic tone is of use also during the performance of voluntary movement. In ordinary circumstances a patient who has been subjected to the operation of sympathetic ramisection cannot detect any disability in consequence of the loss of the sympathetic nerve supply of his voluntary muscles. However, to test this matter closely I have observed the effect of sympathetic denervation after the exercise involved in the flight of a bird. During the flight of a sea-gull in which the unilateral operation has been performed, no obvious difference is to be detected in the movement of the two wings. After completing a flight of one hundred metres, however, the position of the wing on the operated side is in marked contrast to that on the normal side (see second lecture). It is drooped and abducted to a remarkable degree, although hardly any deviation from the normal position may have been visible prior to undertaking the flight. The explanation of this observation seems to be that plastic tone enables the fixing muscle fibres to follow up the contraction of the active fibres and assist in maintaining the intermediate positions assumed at all stages of the movement. When plastic tone is removed, voluntary effort is increased in order to maintain these intermediate positions against the action of gravity as well as to perform the movement.

It appears, therefore, that in voluntary movement postural tone, made up of a contractile and a plastic component, is first inhibited; the "movement" muscle fibres then contract and are assisted in maintaining the advantage gained by the plastic tone of neighbouring "fixing" fibres which are passively shortened; and finally cortical impulses determine that contractile tone is exhibited in the muscles whose contraction is necessary to confer the required position upon the body; the length of the muscle when this position is attained is maintained by plastic tone exhibited by "fixing" muscle fibres.

In certain cases of spastic paralysis plastic tone is in excess. This interferes with voluntary activity, because it is imperfectly inhibited at the outset of voluntary effort. When excessive voluntary effort initiates movement the exaggerated degree of plastic tone, which is present in both agonists and antagonists, as Dr. Royle has shown, tends to provide resistance to the execution of the movement by

# PYLORIC STENOSIS IN INFANTS.

FEB. 28, 1925]

fixing, to an abnormal degree, the length of the muscles of the limb at all the intermediate positions through which the moving part passes. In this way the effects of diminished voluntary power are enhanced in degree on account of excess of plastic tone, which is no longer adequately controlled by the cerebral cortex. In fact this defective control is not infrequently the greater disability, and an account of it the voluntary motor pathway may be unable to function to the full extent of which it is capable. This desideratum is attained by removing the plastic tone entirely, when the rigidity of the muscles disappears. The result is that the initiation and the execution of voluntary movement are both improved.

Dr. Royle found that one patient, with a gunshot wound of the cerebral cortex, who illustrated the presence of excess of plastic tone to a striking degree before the operation, was able to inhibit the tone of the extensor muscles of the knee following ramisection. He was unable to flex the knee voluntarily, but he could inhibit the tone of the muscles sufficiently to let the leg fall into the flexed position. This was impossible prior to inhibit plastic tone. After ramisection he was able to inhibit the contractile component of tone which alone remained. This patient illustrates that the cerebral cortex normally inhibits both components of postural tone, and that injury may affect the control over the plastic component to a greater extent than that of the contractile element. This accounts for the marked improvement in control which follows sympathetic ramisection.

Consideration of these facts reveals the far-reaching influence in the interpretation of the functions of the cerebrum and cerebellum the further investigation of the central control of muscular tone is likely to exert.

[Hunter was in the midst of his experimental work when he received the invitation from the American College of Surgeons to deliver the Murphy Oration in New York. He and the team of collaborators who were inspired by his enthusiasm were preparing to investigate a host of problems—anaatomical, physiological, pharmacological, and clinical—suggested by this work; and it was with the utmost reluctance that he left his laboratory last September. But he realized the value of a personal exposition of his results, and felt it his duty to accept the invitation from America. He fully realized how profound a revolution his work was destined to create in anatomy and physiology; and it is unspeakably tragic that he was not permitted to develop these investigations himself.

I refer to these matters to call attention to the fact that circumstances forced Hunter at times when he had announcements of his results at times when he had their incompleteness. One of these I have just mentioned—the call to New York just at the moment when he had got a clear vision of the host of fascinating problems, the solution of which seemed to be made feasible by his working hypotheses. The first announcement of his work on the sympathetic was made in 1923, during the Association in Sir William MacEwen to the British Medical Association in Australia. The work was then still in the early experimental stage; but as the results were being applied to surgery it became necessary to explain the purpose and the principles underlying it for the guidance of those surgeons who felt it their duty to make use of a procedure that seemed to afford a certain hope of alleviating the chief troubles of the spastic paralytic patient.

Hunter had become keenly interested in the problems of the influence of the sympathetic upon visceral functions (which have not been discussed in these lectures); and if he had lived he had intended to embark upon a far-reaching inquiry as to the similarities and differences between the non-striated, cardiac, and striated muscles, and to correlate the actions of the sympathetic system on all three kinds of muscle.

In preparing these lectures for publication I have made free use of the work of Dr. T. K. Potts, published in the *Journal of Anatomy* (January, 1925), and the reports of the Murphy Oration in *Surgery, Gynecology and Obstetrics* (December, 1924); and I have to express my thanks to the editors of these journals (Sir Arthur Keith

and Dr. Franklin H. Martin) for their generosity in allowing me to quote freely and copy illustrations. The drawings illustrating these lectures were made by Mr. T. Poulton, mostly from illustrations selected by Hunter himself. Dr. John Beattie and Miss Audrey Russell made special dissections for me to check some of the anatomical points in the relations of the sympathetic rami in man and the fowl. Professor Hunter is in no sense responsible for Figures 2 and 14, which I constructed to give pictorial expression to the implications suggested in his argument.—G. E. S.]

## THE EARLY DIAGNOSIS AND TREATMENT OF PYLORIC STENOSIS IN INFANTS.\*

BY  
 HUGH T. ASHBY, B.A., M.D.CANTAB., F.R.C.P.,  
 VISITING PHYSICIAN TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL,  
 AND  
 A. H. SOUTHAM, M.D., M.Ch. Oxon., F.R.C.S. Eng.,  
 ASSISTANT SURGEON TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL.

A CLEAR understanding of the nature of pyloric stenosis in infants and the recognition of the importance of early diagnosis, and so treatment, are most essential. We are quite sure that if the condition could be recognized early many lives would be saved. It is more common than is usually thought. By pyloric stenosis we mean a great hypertrophy of the circular and longitudinal muscles which control the passage of food from the stomach to the duodenum. The muscle here becomes enormously thickened and hypertrophied, so as to block the pyloric canal. The consequence of the block is that the stomach wall also increases in thickness and size as it tries to force its contents through the constricted opening into the duodenum. The food, not being able to pass through the pylorus, is forced the opposite way up the oesophagus, and we get the forcible vomiting so characteristic of the disease.

### DIAGNOSIS.

**Sex.**—In the great majority of cases the infant is a boy, but the cause of this is quite unknown. This fact, however, is a help in diagnosis. Eight or nine out of ten cases are boys.

**Place in Family.**—Many cases occur in the first-born; this looks as if the mother had not been able to produce a perfectly normal infant, but one different in some way. There is, by the way, a special liability of first-born children to abnormalities.

**Age.**—The condition is often called "congenital hypertrophic pyloric stenosis." This term is somewhat misleading and wrong, for the infants are, for a time anyhow after birth, perfectly well, and they show no symptoms till they are a few weeks old.

**Symptoms** do not appear till the infant is at least two weeks old, and the commonest time for the vomiting to start is from two to four weeks after the age of six weeks.

**Vomiting.**—This is perhaps the most characteristic sign. Vomiting takes on the character peculiar to the disease. The vomiting is forcible, and the food is shot out of the mouth, as he lies in his cot. The infant does not vomit after each feed, but usually twice or three times a day, but when it does vomit more than one feed comes up at a time. The infant who vomits after each feed does not usually have pyloric stenosis. The vomit often has much mucus mixed with the food, showing that the stomach has become inflamed.

**Constipation.**—As the vomiting begins the infant becomes constipated to a marked degree. The bowels are only moved by enemata, and then only a little at a time. The reason being that little food gets through the pylorus. The intestines become atrophied from disuse, and this is a hindrance after operation, when the food gets through the pylorus.

\* Read before the Lancashire and Cheshire Branch of the British Medical Association on November 20th, 1924

into the intestines. The vomiting of ordinary digestive disturbances is associated with diarrhoea, not constipation.

*Wasting* becomes rapid simply from lack of food and fluid, which are not retained, and the child may easily lose 4 or 5 ounces a day. Another characteristic sign is that the baby is greedy for the feeds and takes them well. This is quite unlike the ordinary dyspeptic infant.

*Peristalsis*.—Waves of peristalsis may be seen passing across the abdomen, due to contractions of the stomach, and they are best noticed while the baby is having a feed. This peristalsis may be seen in other conditions, but it is specially well marked in pyloric stenosis.

*Tumour*.—The pyloric tumour is usually situated about an inch above the umbilicus, under the right rectus. Some observers state that they can feel the tumour in a high percentage of cases. Personally, we lay little stress on this, as it is often an exceedingly difficult matter to feel the pylorus. The infant is generally cross and holds the abdomen too rigid, and even under the anaesthetic the tumour frequently cannot be felt, as it may be placed deeply under the liver. The failure to feel the hypertrophied pylorus should not prevent a diagnosis of pyloric stenosis.

The reason that cases of pyloric stenosis are often not recognized, or recognized late, is that the food is thought not to agree, and that it is in consequence of this the infant vomits and wastes.

Two things may occur in infant feeding: the baby's food may be wrong and the baby right—this is the commonest thing to happen; or, as in pyloric stenosis, the food is right and the baby wrong. A baby with pyloric stenosis is weaned from the breast because he vomits; the food is thought to be wrong. The vomiting, however, persists, no matter what food is tried, and the breast milk is lost. A baby should never be weaned without a very definite and good cause.

#### TREATMENT.

The treatment of pyloric stenosis in infancy may be either medical or by operation. It is only within recent years that the real value of operative treatment has been recognized. Directly the condition is diagnosed we are quite convinced that surgical intervention alone will give the best results. In the past much valuable time has been lost by trying medical treatment. Medical treatment has undoubtedly been successful in a certain number of cases, but it is not improbable that some of the cures were really cases of pyloric spasm, and not hypertrophic stenosis. It is doubtful if cases of well marked hypertrophic stenosis are often cured except by operation. As already stated, the condition found is one of true hypertrophy of the pyloric ring, producing obstruction to the outlet from the stomach. Any treatment to relieve this must provide a free exit from the stomach, and experience has shown that this can only be satisfactorily obtained by operation. Further, the ideal operation is obviously one that restores the continuity of the alimentary canal through the pylorus.

#### Rammstedt's Operation.

The best procedure at the present time is that described by Rammstedt in 1912, and taken up in this country in 1918. This operation consists in transperitoneal incision of the hypertrophied pyloric ring, leaving the mucous membrane intact, thereby restoring the continuity of the alimentary canal. This method has now become widely adopted, and we ourselves are so convinced of its superiority that we carry it out in every case where surgical treatment is decided upon. To anyone familiar with the technique it is easy and quick to perform, and has such obvious advantages over other methods of treatment that it has received almost universal approval, whilst the fact that no suturing of the stomach or intestine is necessary makes it an extremely simple operation. Further, we have met with no cases of recurrence of symptoms necessitating a second operation, as has been recorded after other methods of treatment.

Once operation has been decided upon the pre-operative preparation of the patient is of considerable importance. If the child is in good condition we advise operation at the earliest possible opportunity, as nothing is to be gained by delay. In those cases, however, where symptoms have been

present for some time and the child is in a semi-starved condition a delay of perhaps twenty-four hours is justifiable to introduce fluids and thereby improve the chances of success. All cases are treated as urgencies once the diagnosis has been made. Prior to operation fluid in the form of saline and 2 per cent. glucose is introduced into the body by the rectum and subcutaneous injection, and the infant's weight can by this means be raised by as much as 6 ounces in the twenty-four hours. The stomach is washed out with saline to rid it of curds and other offensive contents; this also renders the stomach itself more healthy.

At the time of operation the child is warmly clad and laid on a hot-water bottle in a well heated theatre. All these details are of importance as they help to minimize shock in an infant which has often little reserve power to spare. With regard to the anaesthetic, we now as a general rule prefer warm ether. We have found this more satisfactory than local anaesthesia and gas and oxygen, owing to the poor relaxation so frequently obtained, which adds to the difficulties and time occupied in the operation.

The abdomen is opened by a 1½-inch incision above the umbilicus to the right of the mid-line. The dilated stomach usually presents and is gently delivered through the wound, the pylorus being thereby readily identified. The stomach is then held by an assistant, and this both draws down the pylorus and leaves the operator the free use of both hands. The pyloric ring, which appears as a hard white cylindrical swelling, is incised longitudinally along its upper border with a sharp scalpel. In this situation there are usually no vessels of any size and the bleeding will be practically negligible. The incision is carefully deepened with a blunt dissector till the mucous membrane beneath bulges freely into the gap. In this, the essential step of the operation, two dangers must be watched for: First, haemorrhage, and this can be avoided by making the incision as described, whilst any vessel that may be cut should be under-run and ligatured. Secondly, if the incision is prolonged too far into the thin-walled duodenum the mucous membrane may be wounded and result in leakage of the contents; this can be avoided by dividing the muscle with the blunt dissector rather than with the scalpel.

Having successfully completed this stage and seen that there are no bleeding points, the stomach is returned to the abdominal cavity and the wound closed, saline being introduced into the peritoneal cavity meanwhile. With ether anaesthesia little difficulty will be found in closing the small incision, and the whole operation should take less than ten minutes to perform.

To secure success in these cases, rapidity in operating and the least possible amount of handling of the viscera are of vital importance. Both of these conditions are attained in the Rammstedt operation, and shock is thereby reduced to the minimum. The child should be given saline immediately after the operation, and fluids by mouth are allowed as early as possible. Whenever possible the mother should be encouraged to suckle the baby; this we regard as one of the most important steps in the after-treatment. A doubtful case may be brought through successfully if the mother's milk is available for the child. If breast-feeding is not possible, peptonized milk is likely to suit the baby.

#### PROGNOSIS.

The prognosis depends largely on the duration of symptoms and the condition of the child when submitted to operation. In early cases there is usually a rapid improvement immediately following operation. If the patient has been ailing for some time and there has been a progressive loss of weight and it is in a semi-starved condition, the mortality is bound to be high. Recovery after operation is uncertain in babies weighing less than 7 lb. As, however, the disease is becoming more readily recognized—and the symptoms are so typical that mistakes should seldom be made—the prognosis will become increasingly more favourable. With earlier diagnosis and opportunity to operate before the child is wasted and collapsed, the death rate should be reduced to less than 10 per cent. This ideal will only be attained when cases are recognized sooner.

In considering the results of treatment, statistics collected from the Hospital for Sick Children, Great Ormond Street, London, show that, during the years 1915-17, 54 cases were

ated, the majority without operation, and the total mortality was 80.5 per cent. Prior to the introduction of the Rammstedt operation in 1918, the operative mortality in this hospital was 100 per cent., not one single case being recovered after operation. In the following year, when the Rammstedt operation was adopted, it fell to 41 per cent. after surgical treatment, whilst in 1923 for 55 collected cases the operative mortality was 29 per cent.

During the past twelve months we have operated on 10 cases, with 5 deaths. This gives a death rate of approximately 30 per cent. Death occurred in 2 cases within twenty-four hours of operation, and was due to post-operative collapse in weakly and debilitated infants. In cases it occurred four, seven, and twelve days later, and appeared to be due to gastro-intestinal disturbances and inability of the infant to assimilate its nourishment.

In cases with a long history it is not unusual to find the testicles small and shrunken when examined *post mortem*, and it appears that death is due to their atrophy from disuse and their failure to recover their digestive function. The average age in these cases was 7 weeks, and the duration of symptoms twenty-one days. The condition most commonly appears in the third week of life.

Whilst fully realizing that the figures here cited are too small to allow deductions to be drawn, they serve none the less to illustrate the average results of surgical treatment of the disease at the present time.

#### CONCLUSION.

We would conclude by again urging that, once the condition has been recognized, surgical aid should be sought at the earliest possible moment, for in operation lies the quickest and most certain chance of success.

After surgical treatment the infant usually shows rapid improvement and within a few weeks is frequently able to be discharged as cured. Medical treatment, on the other hand, may require months of careful attention, and the ultimate result is often uncertain. If recovery takes place after operation it appears to be permanent; in fact, the majority of those who recovered after operation in infancy are in later life a good deal above the normal weight for age.

## A NEW TUBERCULIN.\*

BY

ALEXANDER LUNDIE, B.Sc., M.B.Ed.,  
D.C.M.S. (PATHOLOGY) MINISTRY OF PENSIONS, W. MIDLAND REGION.

Organic analysis is not likely to yield any single substance capable of producing antibodies to the tubercle bacillus, and if it is carried too far it is not even likely to yield any mixture of substances capable of antibody formation. The most efficient antigen is likely to be a suspension of culture or of pulverized bacilli in normal saline. There are technical difficulties in the way of obtaining ideal products, and these difficulties are aggravated when the antigen is required for immunization experiments or for therapeutic use.

Bevredka's antigen is prepared at a high temperature, and most tuberculins are made from bacilli killed by heat. The analytical processes employed to determine the composition of tubercle bacilli mostly involve the use of heat, to kill the organisms if for no other purpose. Heat is required for extracting the acid-fast material from the organisms. I know of no simple solvent that can extract this substance without the prolonged action of heat. A number of observers have noted that hydrochloric acid added to a simple fat solvent is able materially to assist the process of extraction.

If any chemical substance could be found to dissociate this acid-fast substance from its union with other constituents of the bacillus, at a comparatively low temperature and without loss of time, it would make the protein constituents of the bacillus more easily accessible to simple solvents, and would yield them up in a state more nearly resembling the parent substance. Phosphorus trichloride seems to have

this action, but it also reacts with the protein constituents of the bacilli. Very definite considerations led to the use of this reagent for the purpose of preparing a tuberculous antigen directly from living organisms. It is not always possible to foretell exactly what will happen when a new reagent is tested. A number of reagents were previously tried, with more or less futile or even alarming results. The process adopted is offensive, and must be conducted with due precautions for safety. Phosphorus trichloride gives a colour reaction with all bacilli and with other organic substances containing protein. The colour is purplish-brown. Enough water must be present to act catalytically; too much will interfere with the reaction, and there will be no reaction with absolutely anhydrous materials. Under proper conditions violent effervescence takes place, and a voluminous evolution of irritating fumes occurs, which cause coughing and headache, which may last for several days.

Although the original mixture is liquid, the end of the reaction is indicated by its becoming a firm pasty mass, which can be liquefied by the addition of water. All the bacilli can be precipitated along with the phosphorized fats by the addition of acetone. This precipitate is the basis of the tuberculin about to be described. Its antigenic action is feeble, but is much enhanced by cholesterol.

Sound guinea-pigs bear relatively large doses of tuberculin, but tuberculous animals are readily killed in thirty-six to forty-eight hours by comparatively small doses. A healthy animal bore a large dose of this new preparation with impunity. A seriously diseased animal also bore the same dose, and even appeared to be better twelve hours afterwards. Twenty-four hours later a second dose, even larger than the first, was given, and borne equally well. Forty-eight hours after the first dose a third dose was given, and next day the animal was markedly better in health. Clearly this substance had not the lethal property of old tuberculin towards tuberculous animals. Its therapeutic action on the same animal was then tried. A weekly dose was thereafter administered until all the enlarged glands became palpable, while the animal actually became the healthiest and heaviest in the establishment. When it was at last killed no trace of the diseased glands could be found, but there were a few scars of healed tubercles in the spleen, and an area of perisplenitis. An emulsion of the spleen injected into another guinea-pig produced no disease.

The various strains of human and bovine tubercle bacillus differ in virulence, so a culture of bovine bacilli of well established virulence was obtained from the National Collection of Type Cultures for the purpose of the next experiments, which were performed on rabbits.

The rabbit never survives an infection of bovine tuberculosis, no matter how contracted. If the bacilli be inoculated into one of the hind limbs an enlargement soon arises. After the swelling upon the mass of the bacilli inoculated, general symptoms supervene. General military tuberculosis sets in and rapidly kills the animal. On post-mortem examination none of the lesions shows any evidence of circumscription. They tend everywhere to spread diffusely.

Five young rabbits were each inoculated intraperitoneally with 5,000 million virulent bovine tubercle bacilli. One was kept as a control without subsequent treatment. In six days its temperature had risen two degrees, and in eleven days four degrees. Its weight varied, reaching a maximum in eighteen days; it died in thirty days, weighing exactly the same as at the beginning.

The second rabbit was treated with the new tuberculin. It gained weight for twenty-one days. It was accidentally injured, and died on the twenty-second day.

The third rabbit became ill five days after inoculation. On the eleventh day its temperature was 105.3° F. Treatment was then commenced. It gained weight for thirty-one days, but the temperature remained high, and it died on the fortieth day.

The fourth rabbit became ill one day earlier than the others. Treatment was commenced on the tenth day, and it died on the thirty-fifth day.

The fifth rabbit became ill on the sixth day. Treatment was begun on the eleventh day, but in this case human, not bovine, tuberculin was used. All the other rabbits were treated with bovine tuberculin. This animal trebled its weight in fifty-five days. The local infection soon became sharply delimited from the surrounding healthy tissues and began to heal. The animal was killed at that stage on account of my holiday arrangements. *Post mortem* the lungs showed large, well defined tubercles in process of healing.

\* A paper read before the Birmingham Branch of the British Medical Association, November 20th, 1924.

A pair of larger rabbits was infected by the subcutaneous instead of by the parenteral route. Both were decidedly out of sorts in seventeen days. Treatment was commenced on the twenty-sixth day. The first had already begun to decline seriously eight days before, owing to the infection having been intentionally accelerated by massage of the infected glands. Tuberculin of human origin was administered to both animals, but the first died thirty-five days after infection, without having made the slightest sign of rallying.

The second rabbit of this pair was seriously ill within sixteen days of infection, and treatment was commenced ten days later, and continued to the fifty-sixth day after the original infection. Only seven doses of tuberculin were given altogether. This animal increased in weight long after treatment was stopped, for nearly five and a half months. Eventually it was seized with nasal catarrh and signs of pneumonia. Nasal catarrh had never been observed in any of the other animals; it was probably a superadded infection by one of the pasteurilla group of organisms, and on this supposition the animal was promptly killed. *Post mortem* large healing tubercles were found in both lungs as well as fresh haemorrhagic patches. The site of infection was completely healed, but there was a large subscapular tuberculous gland, circumscribed by healthy tissue, though otherwise certainly capable of rekindling the infection.

This case and the last one of the other series were both decidedly encouraging, because rabbits at the best are difficult to manage under experimental conditions. Many die from accidental causes, and it says much for the care and skill of my assistants that the death rate of both rabbits and guinea-pigs is the lowest that I ever heard of. All these animals were very severely infected before treatment commenced, and they were all treated with very excessive doses of tuberculin. Not one reacted fatally to this excessive dosage.

Man has a much greater natural resistance to tuberculosis than the guinea-pig or rabbit, and his treatment is accordingly more satisfactory. Still, I have little fear about the results of my next animal experiments, if I think it necessary to resume them. As soon as it was thoroughly ascertained that the use of this tuberculin was perfectly safe for animals, I took advantage of the courtesy of Mr. Gemmill, and later of Mr. Naughton Dunn, who enabled me to treat cases of lupus vulgaris and of surgical tuberculosis. These cases responded very favourably.

Lupus erythematosus has responded to treatment even more rapidly than lupus vulgaris. But I consider an apparent cure not to be beyond danger of relapse, and would advise further treatment for eighteen months. I am indebted to Mr. Yates and Mr. Heath for cases of this disease.

I am indebted to Dr. Taylor of Syston, Leicester, for the first reports on the treatment of pulmonary tuberculosis with this tuberculin. I deliberately avoided treating this disease until I had studied the effect of treating the other forms of tuberculosis. Encouraged by Dr. Taylor's reports on advanced chronic cases, I undertook the treatment of a very advanced case of phthisis. I am indebted to Dr. Castellain for an introduction to this case, and to Dr. Garbutt for permission to attend and give the necessary treatment.

There were physical signs in both lungs and large cavities in the upper lobe of the right lung. The prospects were as hopeless as could be desired for the trial of a new method of treatment, and in that opinion we all concurred. The patient was aged 23, was quite sure she was recovering. She had three doses of the bovine tuberculin, followed by a course of antogenous tuberculin, beginning with a dose of a milliliter of a gram. All anorexia rapidly ceased, the appetite became excellent, and sleep was restored; sweats ceased, sputum was reduced from about two pints a day to about a quarter of a pint. The pulse became regular and much slower (144 at first, afterwards 88), respiration was calm, tubercle bacilli were comparatively scanty in the sputum, and the physical signs greatly improved. The temperature became more equable, but was slower in coming under control than any other symptom. Flesh was put on quite obviously.

Later the patient had a complete pneumothorax of the right side. The temperature rose to nearly 103°, but it afterwards returned to normal, and she made some progress. Nineteen days after the occurrence of the accident the lung apparently collapsed again suddenly and death quickly ensued. She had been examined regularly all the time, and the lung was found to be expanding.

The principle I have enunciated is probably applicable to the treatment of leprosy and certain other diseases. The nasitin treatment of leprosy by Professor Deycke of Constantinople is akin to it, but nasitin is very toxic.

I am indebted to the Director-General of Medical Services, Ministry of Pensions, for permission to publish this paper.

## PLEURAL REFLEX ASSOCIATED WITH FRACTURE OF THE TWELFTH RIB.

BY

GLADYS M. WAUCHOPE, M.D., M.R.C.S.,

HOVE.

THE following case seems worthy of record as a striking and unusual complication of fractured rib.

An unmarried woman, aged 41, fell from a stool on the night of July 15th, 1921, striking her back against a chest of drawers. There was no abrasion of the skin extending vertically upwards from a point below the level of the last rib about four inches from the right border of the spinal column. The twelfth rib was fractured about midway between its junction with the vertebra and the abrasion.

Strapping was applied, and the patient remained in bed, experiencing, for the first few days, considerable discomfort and pain even on slight movement. Four days after the accident she had an attack of hiccup lasting for some hours; both before and after this she had an occasional single hiccup. Progress was otherwise uneventful, and on July 28th the patient got out of bed for the first time. The next morning, when out of bed, she stooped for something and was suddenly conscious of a feeling of faintness, breathlessness, and palpitation, accompanied by severe pain in the upper part of the sternum. She felt very ill and thought that she was going to die. When seen an hour later she was pale, anxious, and dyspnoeic. The pulse (136 a minute) was feeble, and small, but regular. The heart was not enlarged. Harsh, rapid, and shallow breath sounds were heard all over the lungs. There were no areas of diminished resonance and no adventitious sounds. The temperature was 99° F. Adrenaline and cardiac stimulants were administered and the breathing improved; the general condition, however, remained serious during the day. In the evening the pulse rate was still 135, and the temperature had risen to 100.8° F. There were no physical signs in the chest and no pain at the site of fracture.

After this improvement was steady. The pain in the upper part of the sternum was continuous until the third day; it was not increased by breathing or movement. The temperature fell gradually, and was normal on July 31st (fourth day). On August 2nd the pulse rate was 72, the respiration rate 20, and the general condition good. The patient was allowed to get up. From about August 1st onwards, when all acute symptoms had subsided, involuntary sighs occurred from time to time, seeming to the patient to arise from the mid-sternal region. They continued two or three times a day for about a week, ceasing gradually. There was no further interruption to convalescence.

It seems probable that the sudden movement of stooping irritated the nerves of the pleura, either by tearing an adhesion or by friction, and so gave rise to a pleural reflex of the vasomotor type.

A consideration of the anatomy of the part shows that the pleura and diaphragm are in close proximity to the twelfth rib at the site of fracture, the external arcuate ligament of the diaphragm being attached to the tip and lower margin of the twelfth rib and to the transverse process of the first lumbar vertebra. The lung is above, reaching only to the eleventh rib, while the pleura extends to below the twelfth. In the normal subject the kidney would be liable to injury through the pleura and diaphragm, but in this patient it was movable and well below the level of the rib.

Pleural reflex or pleuro-pulmonary reflex has usually been recorded in connexion with operative thoracentesis. Stivelman<sup>1</sup> concluded that in over 75 per cent. of cases there was injury to the visceral pleura and underlying lung tissue. Capps,<sup>2</sup> however, has shown experimentally that the reflex can be occasioned by irritation of the pleura alone, the healthy pleura being much more tolerant than inflamed pleura. It is probable that, in the case reported, the pleura had been injured. The patient experienced more pain and discomfort than usually attend simple fractured rib, while the hiccup during the first week points to involvement of the diaphragm and therefore of the diaphragmatic pleura. The inflammatory reaction may well have persisted till the thirteenth day, when the cardio-respiratory symptoms occurred.

The sighing which arose during convalescence calls for some comment. Physiologists explain sighing as a deep inspiration following, and compensating for, a temporary cessation of breathing.<sup>3</sup> Various causes which depress the respiratory centre may give rise to sighing—for example, cerebral anaemia and the excessive use of tobacco. It also occurs when the mind is deeply engaged, so that people unconsciously sigh at their work.

In the case under review a cause for suppression of respiration might be found in the injured pleura and

diaphragm; or, since the patient was up and about, the sighing may simply have resulted from cerebral anaemia connected with the recent vasomotor disturbance.

## ARSENICAL POISONING TREATED BY SODIUM THIOSULPHATE.

BY

HILDA M. HALLIDAY, M.R.C.S., L.R.C.P.,

AND

CHARLES E. SUTHERLAND, M.B., B.S.MELB.,

M.R.C.P.LOND.,

ASSISTANT MEDICAL OFFICERS, ST. PANCRAS HOSPITAL, LONDON.

The following case is of importance as a sequel to the communication from Dr. H. C. Semon in the *BRITISH MEDICAL JOURNAL* of April 12th, 1924.

A woman, aged 30, became infected with syphilis towards the end of her fourth pregnancy. She had been treated by intravenous injections for ten months, and had then been advised to take six weeks' rest from treatment. Three weeks after the last injection, and five weeks before she came under our care, she became jaundiced, and noticed loss of power in the arms and general weakness; she passed dark urine and pale stools. For seven days prior to admission she had vomiting, anorexia, constipation, insomnia, and failing vision.

On admission there was deep generalized jaundice, the mouth was dry and dirty, and answers to questions were correct but monosyllabic and very slow. There were no physical signs of neuritis, but the hands could not be lifted, and the vision was bare perception of light. The liver dullness was diminished; the urine contained albumin and bile.

While awaiting a supply of chemically pure dehydrated sodium thiosulphate we gave the patient 30 grains of the stock salt in

solution by the mouth every four hours, and continued this method of administration throughout the first week. There were no resultant toxic symptoms (colic or diarrhoea), but there was no arrest of the arsenical symptoms. By the third day the patient was apparently moribund; she vomited frequently and in excess of intake; she was restless, apathetic, and doubly incontinent; the bowels acted only after enemata.

At this stage the first intravenous injection was given, and for ten days the patient had 0.45 gram daily, followed by seven similar doses on alternate days, making a total of 7.65 grams spread over a period of twenty-six days. In addition, during the first week she took about 80 grams by the mouth, but probably much of this was lost by vomiting. From the first intravenous injection the downward trend was arrested. After five doses the mental condition was perfectly clear, muscular power of the arms was good for all movements, and the patient could read small print. She was still jaundiced, incontinent, and vomiting. There was still bile in the urine, and leucine was seen in the deposit. At the end of the third week she was convalescent and able to be up for half the day, eating well, and not vomiting; the jaundice was almost gone, and the urine normal.

The levulose tolerance was tested and seemed to show a definite derangement of liver function during the height of the illness, with rapid recovery under treatment. The deterioration in her general condition during the first two days clearly demonstrated the progressive nature of the disease and emphasized the remarkable improvement following intravenous administration of the specific remedy.

Levulose Tolerance.	April 25th.	May 13th.
Fasting blood sugar ... ..	0.131	0.103
Half an hour after levulose ... ..	0.137	0.086
One hour after levulose ... ..	0.218	0.100
One and a half hours after levulose ... ..	0.206	0.166
Two hours after levulose ... ..	0.206	0.100

We should like to express our thanks to Dr. Thackray, Medical Superintendent, for permission to publish this case.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### MALIGNANT CERVICAL ADENITIS SIMULATING ANEURYSM.

THE case here recorded, though disappointing from a diagnostic point of view, is interesting as illustrating how very closely cervical adenitis may simulate aneurysm. An exploring needle would have settled the diagnosis, but as nothing was to be gained by the procedure it was not carried out.

A woman, aged 79, was admitted to the Tooting Bec Hospital in August, 1923. She showed evidence of specific disease, and her history confirmed this. On October 14th, 1924, she suddenly developed a tumour about the size of a hen's egg above the right clavicle. As far as can be ascertained this took only about a week to become apparent. The tumour was slightly irregular in shape and was distinctly expansile. Two little flaps, one on either side of it, separated about a quarter of an inch with each beat of the heart. The heart rate was 66 and the blood pressure 130. There was no appreciable difference in the two radial pulses, but the right radial pulse gave a tracing exactly similar to that of a subclavian aneurysm portrayed in Hutchison and Rainy's *Clinical Methods*. There was a distinct systolic bruit over the aneurysm and over the aortic area. This is interesting as an illustration of a contribution I sent to the *JOURNAL* some time ago entitled "An aortic murmur."

A month later the tumour was noted as much larger—the size of a small orange—and the radial pulse as being much altered. The patient was treated with potassium iodide, being rapidly advanced to 40 grains every four hours, and showing no unpleasant symptoms from the drug. The size of the tumour in a week's time was distinctly less and there was a constricting band at the back of the mass. The following week the mass increased in size and the potassium iodide was discontinued. The blood pressure was 135, and the radial pulse tracings were similar, with no morbid characteristics. All this time there was little or no complaint of pain, and the patient died on December 5th from a low form of terminal pneumonia.

At the necropsy a large mass of cancerous glands was found completely encircling the subclavian and carotid arteries with secondary deposits in the mediastinal glands and deep in the liver.

The diagnosis made was a carotid aneurysm involving the subclavian and possibly innominate arteries, and several persons of wide experience saw the patient and found no

fault with the conclusion arrived at. When the change in size was brought about by administration of potassium iodide it was thought that that clinched the diagnosis. The systolic bruits were, of course, caused by compression of the artery, and not by the constriction at the entrance or exit of an aneurysmal sac.

I am indebted to Dr. E. H. Beresford for permission to publish the case.

Tooting, S.W.

THOMAS LINDSAY, M.D.,  
F.R.C.S.Ed.

#### IMMUNITY, SPECIFICITY, AND NON-SPECIFIC FACTORS.

IN the issue of December 13th, 1924 (p. 1098), Dr. R. A. O'Brien says: "It may be that the administration of *coli* vaccine does materially influence the course of typhoid fever and of arthritis, but we feel that we must have more evidence before accepting the claim." In view of this the following case of colitis and arthritis cut short by an attack of typhoid fever, and the recovery from the typhoid fever, is of interest.

A girl, aged 18, suffered since the age of 13 from attacks of subacute arthritis rheumatism. She had suffered for some years before this from five or six loose motions a day. An examination of the stools showed enormous number of *B. coli*. The arthritis was most probably caused by the colitis. At 18 years of age she contracted typhoid fever. The fever was complicated by severe haemorrhage on the twenty-third day of the disease. Vidal's test was positive. The temperature fell to normal on the forty-second day of the illness, and health and strength gradually returned. The arthritis and stiffness of joints disappeared and have not returned, though it is now more than three years since recovery from the typhoid fever. The motions are now one or two a day.

One case proves nothing, as it may be entirely coincidence, though even coincidence has a cause; but the recovery from the typhoid fever and the cutting short of arthritis and of colitis appear to me to be sufficiently interesting to record, especially to those who successfully treat typhoid fever by *coli* vaccine, or those who successfully treat arthritis by intravenous injections of *B. coli* or typhoid bacilli.

Queen Camel, Somerset.

J. E. BOLTON.

## Reports of Societies.

### THE MILK SUPPLY AND HEALTH.

At a meeting of the Medico-Chirurgical Society of Edinburgh held on February 4th, the President, Sir DAVIN WALLACE, in the chair, Sir ROBERT PHILIP opened a discussion on the milk supply of the country and its bearing on health.

Sir Robert Philip pointed out that in February, 1913, a committee of the society had been appointed to inquire into the relation between the milk supply of Edinburgh and the prevalence of tuberculosis. The committee came to the conclusion—largely on the findings of Mr. Fraser and Mr. Mitchell—that the infection of children with bovine tuberculosis was prevalent in Edinburgh. It recommended: (1) that the members of the society should advocate strongly the advisability of boiling milk, (2) that the town council should be asked to reorganize milk examination and the supervision of cows, and (3) that the Government should be urged to carry through at an early date a milk bill along the lines of such bills as had been previously considered by Parliament. The further efforts of the society had been interrupted by the war. Reference was made to the Milk and Dairies (Scotland) Act, 1914, and the causes for its delayed operation due to the war. The Amendment Act of 1922 was also cited; it was probable that this Act would come into operation in September, 1925. Among other important provisions the Act allowed the Scottish Board of Health on January 1st, 1923, to make regulations for the production and sale of graded milk and to grant licences to producers and dealers accordingly. In June, 1923, the Board issued a Milk (Special Designations) Order (Scotland), and later a short Amending Order regarding the conditions applicable to pasteurization. Apart from pasteurization three grades of milk were recognized, which were shortly summarized. Since this Order was passed there had been a marked increase of interest and activity amongst producers in the direction of higher grades of milk. In England on December 31st, 1920, the number of licences for the production of certified milk was 9; on December 31st, 1923, it was 55. In Scotland at present there were 9 licences for the production of certified milk, and 19 for grade A (tuberculin tested) milk. Reference was made to the experimental dairy farm at Gracemount, under the management of the Royal Victoria Hospital Tuberculosis Trust of Edinburgh. The purpose of grading milk was then discussed, the essential point being cleanliness. The composition of milk was briefly detailed and some observations were made about its bacteriological content. It was estimated that 50 per cent. of milk cattle in this country were tuberculous, 2 per cent. being in an advanced state of tuberculosis. Much attention had been devoted to the question of freeing herds from tuberculosis in Denmark and the United States, and more recently in Great Britain. Bang's experiments in Denmark were cited. Reference was made to the danger of contamination from the milker's hands, etc., and to the question of housing cattle, with comments on the habits of milkers, the mode of milk transit, and the process of bottling in many dairies. Sir Robert Philip then outlined the present outlook, and referred to the need of close veterinary inspection, a healthier life for cows, instruction to dairy workers in cleanliness, and the significance of proper cooling of milk. Many of these objects had been achieved by the influence of the National Clean Milk Society and similar agencies, while clean milk supply was to be provided it should be plentiful, for the people generally ought to consume more milk. It had been estimated broadly that only about half as much milk per individual was consumed in Great Britain as compared with the United States. Public education was required to popularize milk, and reference was made to some of the methods adopted by American milk vendors to instruct their customers. The producer must also be trained to realize the value of having a sound herd, and that better education of the people would create an adequate demand for certified milk. The providing by some authorities of pre-

served, dried, or tinned milk at child welfare and maternity centres was deprecated. Good milk was at times more difficult to obtain in country districts than in the town. The question of pasteurization was discussed and the risks of inadequately carrying out this procedure were pointed out. If pasteurization was permitted at all it should only be considered a provisional measure, the scientific finger of preventive medicine pointing clearly towards an ultimate goal of a pure natural milk supply. Legislative and administrative measures were mentioned, and also the duty of the medical practitioner in helping to establish the demand for a clean milk supply. In conclusion Sir Robert Philip said, "It is my earnest hope that the discussion will lead somewhere, and that the collective view of the profession may be effectively expressed in support of the legislative proposals and the administrative endeavour by the Board of Health to secure and develop for the nation an abundant supply of sound milk."

Professor T. J. MACKIE discussed the bacteriology of milk. He compared the bacteriological content of milk with that of accepted water supplies, to the disparagement of the former. He referred to some of the organisms found in milk and the dangers which might arise from consuming milk so contaminated. The well known fact was noted that in this country the main hygienic problem in regard to milk are related to tubercle bacilli and the etiology of infant diarrhoea, and the established fact that bovine tuberculosis is commoner in children was cited. He thought that tuberculous milk would still be used for a long time, and that the only immediate remedy lay in destroying the bacilli. Reference was made to infantile diarrhoea and the various causative factors, including the dysentery group of organisms in the severer cases. He doubted the value of pasteurization, since it was a technical process, and therefore might fail; he favoured boiling as the more simple procedure, and the nutritive deficiency of boiled milk could be compensated in infant feeding. Finally he referred to the necessity of education of the public both from the point of view of purity of milk and increased efficiency in the dairy.

Dr. J. F. TOCHER discussed the variations of the constituents of milk in normal cows, the chief variation being in the quantity of butter fat. He drew attention to the difference between the readings of "bulked" milk from a large herd and the readings from individual cows. Under the auspices of the Scottish Interdepartmental Committee on Milk, samples from individual cows were obtained from local authorities all over Scotland throughout every period of the year. These were analysed, and a monograph on the subject would be published this year. The average figures and range of variation in individual cases were shown by means of diagrams: 10 per cent. of the samples gave less than 3 per cent. butter fat. In the case of "solids not fat" 24 per cent. of individual samples gave less than 8.5 per cent., which was the prescribed presumptive limit; this did not show in "bulked" milk from a large herd. The important non-fat constituents were lactose, ash, casein, and albumin. The percentage of lactose varied from 2.7 to 5.5, the numbers for the low percentages being small compared to the high percentages; the reverse held good for albumin. It was noted that a heavy-milking cow on the average gave a higher percentage of lactose than a poor-milking cow; also, the higher the percentage of lactose the lower was the percentage of albumin. It seemed probable that in each individual cow there was a lactose secretion sufficient to secure osmotic pressure in secretion of milk equal to the osmotic pressure of the blood. Age and breed had important bearings on the various constituents of milk. The percentage of butter fat fell in cows from 3 to 12 years: young cows gave a higher percentage of lactose than old ones, while the percentage of albumin was greater in older cows. The percentage of lactose first rose, then fell, during the lactation period, while the reverse took place with albumin. The lactation period showed a wide range—from twelve to sixty weeks. The data regarding the composition of human milk were scanty: in order to get approximate results several thousand samples would have to be submitted to the same careful statistical analysis as that applied to cow's milk.

## PITUITARY DISEASES.

Dr. GERALD LEIGHTON of the Scottish Board of Health discussed the law in respect of the control of the infection of milk with tuberculosis. He first pointed out what the law did not contain, because no full system of control had ever been put into operation in Scotland. He referred to the lack of compulsion in having dairy cows inspected regularly, the failure to slaughter or isolate the tuberculous cows in country districts, and the omission of a health certificate when selling a cow; milk sold in shops was not regularly examined to ensure its freedom from disease. He then described briefly certain aspects of the Dairies, Cowsheds, and Milkshops Orders of 1885, 1887, and 1899, and passed on to certain aspects of the Public Health (Scotland) Act, 1897, in so far as it related to the examination of milk supplies relative to infectious diseases. The Milk and Dairies (Amendment) Act, 1922, was mentioned in reference to the clauses dealing with the sale by farmers of tuberculous milk, but it was pointed out that there was nothing to prevent a farmer from selling a cow with a tuberculous udder. The Burgh Police (Scotland) Act, 1903, was discussed with reference to certain sections which referred to cows and tuberculosis. These provisions did not appear to have been much used owing to technical and other difficulties. The Milk and Dairies (Scotland) Act, 1914, was a very important statute, though its operation was postponed in consequence of the war, and was not yet into operation applied to burghs and districts, and when put into operation would go far to clear up the defects in the existing law. The Scottish Board of Health had power to make it operative on or after September 1st, 1925. In Section 3 it provided that the Scottish Board of Health might require the appointment of veterinary inspectors for the purpose of examining cattle in every burgh and district. In the cattle to be examined once a year in each district. In Section 14 dairymen were required to notify the local authority of the existence of any cow with any sores on the teats accompanied by bleeding or suppuration, or of any cow known to give tuberculous milk. In Section 17 it was provided that milkers must show a medical certificate that they were not suffering from an infectious disease. There was, however, no prohibition from sending diseased cows to market. The grading of milk had made steady progress since it was instituted by an order of the Scottish Board of Health in terms of Section 3 of the Milk and Dairies (Amendment) Act, 1922.

Mr. ARTHUR GORTON, chief veterinary inspector of Edinburgh, described the application of the tuberculin test to cattle. In cattle practice the subcutaneous, ophthalmic, and intradermal tests were employed, Koch's old tuberculin being used. Bovine tuberculin was generally used, but that made from human bacilli of proved potency was as useful. An avian tuberculin test in detail, pointing out the precautions to be taken before the test was performed and during it: he added that a large drink of cold water might temporarily reduce a febrile temperature to normal limits. Tuberculin, he explained, was harmless to pregnant cows provided that parturition was not imminent or they had not recently calved. In the application of the subcutaneous tuberculin test to a dairy herd it was usual to find a decrease of milk secretion which might vary from 3 to 15 per cent. without a single reactor being present in the herd. This decrease was only temporary. Tuberculin was probably a factor in this decrease, but the unusual disturbance and handling of the cows during the decrease, also an undoubted factor in this temporary decrease. Reference was made to the interval necessary between tests; two months was considered adequate. The ophthalmic test and the intradermal or intracutaneous test were then described. Summarizing the comparative value of these tests, Mr. Gorton said that not one of the three was infallible. The subcutaneous test had the highest diagnostic value, despite some of its imperfections; errors would rarely exceed 5 per cent. The ophthalmic test took a place midway between the other two. Under the Milk (Special Designations) Order combined subcutaneous and ophthalmic tests were required in respect of herds supplying tubercle-free milk. Finally, a brief reference was made to the question as to what period of time must elapse after

infection before an animal would react to tuberculin. Experimental evidence went to show that the shortest and longest periods were eight to fifty-one days after infection. From his own experience, if it was desired to eliminate the risk of introducing into a clean herd an animal which harboured infection in latent form, newly purchased animals should be tested at once and again three months later, isolation being maintained during this time. A cinematograph film to illustrate the production of "certified milk" at Gracemount Farm was shown by Dr. J. C. SIMPSON. The preparation of this film was arranged by the Royal Victoria Hospital Tuberculosis Trust, which owns the farm.

Dr. DRUMMOND SHIELDS, M.P., stated that he had long been interested in this question since Fraser and Mitchell had published their results in tuberculosis of bones, joints, and glands, as well as their reports on the frequency of tubercle bacilli in milk. He gave some statistics of the occurrence of tuberculous infection in milk in Manchester, and referred to Griffith's findings with reference to the diminishing frequency of bovine bacilli as ago advanced. He also gave some recent figures for Edinburgh. He urged that the medical profession should acquaint the authorities with the serious position of the milk supply of the country so that parliamentary action might be taken.

Dr. CHALMERS WATSON referred to the difficult question of the relation between the producer of certified milk and the demand for it. He also touched on some of the important bacteriological questions in relation to the subject, and referred to other organisms besides the coliform and tubercle bacilli. He was convinced that the society should make appropriate use of the discussion for educative purposes.

Dr. KEPPIE PATERSON and Dr. JAMES YOUNG urged the necessity of vigorous action to obtain a pure milk supply. A resolution, proposed by Sir ROBERT PHILIP, that the council of the society should be empowered to bring to the notice of all those concerned, including members of Parliament, the urgent need for a clean milk supply, was carried unanimously.

## PITUITARY DISEASES.

A MEETING of the Clinical Section of the Royal Society of Medicine was held on February 13th, with Dr. NEWTON PITT, the President, in the chair.

Dr. DOUGLAS FIRTH showed two cases. The first was a case of Fröhlich's syndrome in a boy, aged 17, who showed extreme obesity with absence of axillary and pubic hair. His memory was defective, and he suffered from frontal headaches. The blood sugar curve indicated the existence of an increased sugar tolerance. X-ray photographs of the skull showed an apparently normal pituitary fossa. Dr. Firth's second case was one of syphilitic anterior and posterior pituitary derangement, exhibiting polyuria, thirst, and hyperglycaemia. A comparison of recent x-ray photographs with those taken some months previously appeared to indicate some thickening in the region of the sella turcica, which was believed to be a bony reaction to syphilitic infiltration. Dr. C. C. BEATTY showed a case of pituitary tumour, with infantilism, in a young man, who had ceased to grow at the age of 13. He was now 4 ft. 4½ in. in height, and weighed 4 st. 12 lb. No hair was present on the face, nor in the axillary and pubic regions. The breasts were enlarged, and the external genitalia were of the infantile type, neither testis having descended into the scrotum. Although the intelligence of the patient was good, signs of an intracranial lesion were present, including optic atrophy and bitemporal hemianopia. The urine was normal and the Wassermann reaction negative. An x-ray examination showed enlargement of the sella turcica. Dr. Beatty advocated operative treatment in this case on account of the progressive failure of vision. Cases of acromegaly were shown by Dr. NEWTON PITT, Sir PERCY BASSETT-SMITH, and Dr. GEORGE RIMMOCH.

Dr. F. PARKES WEBER showed a case of developmental deformity of the right forearm, similar to that occurring sometimes in cases of multiple exostosis (diaphyseal aclasis). The patient, aged 18, was a large and powerfully built young man, with a shortened curved right forearm, and

marked ulnar deviation of the hand. X-ray examination revealed new bone formation in the ulnar concavity along the attachment of the interosseous membrane, similar in nature to that seen in cases of multiple exostosis. Although no exostoses were present in this case the other bony changes were similar to those frequently seen in association with this condition. Mr. PHILIP TURNER showed a girl, aged 14, with enormous and increasing enlargement of both breasts. As he considered that the enlargement was probably due to multiple and rapidly growing fibroadenomata he proposed to amputate, for in his experience x rays had little or no effect upon this condition. Mr. N. ST. J. G. D. BUXTON showed a case of hairy black tongue. The black part was limited to a V-shaped portion of the back of the tongue, and could be removed with gauze. The condition was said to be due to an overgrowth of the fungiform papillae, and, according to the more recent theories, was not associated with the growth of fungi or any special bacteria. This case was discussed by Sir STCLAIR THOMSON, who had seen between thirty and forty similar cases, mostly discovered accidentally during routine examination. Rubbing the affected part with hydrogen peroxide had generally been curative. Dr. C. F. T. EAST showed a case of diabetes insipidus following syphilis, the symptoms of which had been controlled by subcutaneous injections of pituitrin. This case was discussed by Dr. PARKES WEBER, who had had a similar case in which the disease was familial; there was said to have been an unbroken history for two hundred years.

### DISEASES OF THE CLIMACTERIC.

A MEETING of the Chelsea Clinical Society was held on February 17th, with Dr. GORDON LANE, the President, in the chair.

Sir THOMAS PARKINSON opened a discussion on the diseases of the climacteric in both sexes. Many men at this time of life showed changes in arterial tension with or without renal changes. He pointed out the uselessness of attempting to reduce the blood pressure in these cases by means of drugs, and said that alteration in the environment, with lessened diet and rest in bed, were the best methods of relief. He then gave an account of the changes seen in the female at the climacteric. He considered that the flushings occurring at this time were due to the loss of ovarian secretion, and that this loss interfered with the action of the thyroid and adrenals. At this period of life in both sexes the endocrine organs were very erratic in function. The upset of the normal mental condition was due, in many cases, to the thyroid, and the cause of the excessive headaches was, he thought, affection of the pituitary gland. It was most important that men should be treated before definite changes had been established in the vascular system. He believed that people of both sexes ate far too much generally, and that such excess was most harmful at this period of life.

Mr. A. RALPH THOMPSON put the climacteric age as being about 55 to 63 in the male. He showed that sepsis was more common in the male than in the female at this time of life, and that the chief septic changes were associated with gangrenous or necrotic processes. He referred to the occurrence of growths of the bladder, and thought that the practical side of this question was very different from that described in the textbooks. He also drew attention to the comparatively early age at which enlargement of the prostate gland gave rise to symptoms. He operated upon this condition, not so much for the mechanical obstruction that it produced, but because the enlargement so frequently led to disease of the kidney, sometimes chronic interstitial nephritis. He thought that the general rule with regard to growth of the prostate should be the same as that applying to other organs of the body, and said that he had had several patients with malignant disease which had not been anticipated when the enlargement of the prostate was first diagnosed. He thought that to wait for fixity and irregularity of a large prostate was to put off adequate treatment until too late, since these were symptoms of the involvement of other organs. The speaker then reported

certain clinical facts he had observed in connexion with cancer of different parts of the body. He gave figures showing that in malignant cases the thyroid was, on an average, of greater capacity by 6 c.cm. in malignant than in non-malignant cases of death; some of the thyroids in cases of malignant disease were very large. Acting on these and other observations, he had been in the habit of giving calcium and thyroid extract, and in inoperable carcinoma of the bladder some success had been obtained by this treatment. In one case the growth had apparently disappeared and in others it had seemed to make no headway; in some cases weight had been gained by the patients. He thought cancer was a deficiency disease.

Dr. THEODORE HYSLOP pointed out that many men exhibited mental symptoms at about the age of 50, and he thought that this was associated with the periodical retention of uric acid in the system. He advocated saline purges for this condition with diaphoresis.

The PRESIDENT drew attention to the possibility of the patient having started life in a wrong manner, initial errors being emphasized as the patient grew older. He agreed with Sir Thomas Parkinson that the diet was too liberal in many cases. He mentioned, in particular, arteriosclerosis, chronic nephritis, and glycosuria as being the common diseases of this period of life.

### CHOLECYSTOGRAPHY.

At a meeting of the Liverpool Medical Institution on February 12th, Dr. R. E. ROBERTS and Dr. HENRY COLES read a short note recording their observations on cholecystography by Graham's method. This method was based on the use of a salt, opaque to x rays, which, when injected into the blood stream, was excreted by the liver, entered the gall bladder, and was there concentrated, thus rendering the gall bladder under normal conditions opaque to x rays. In their investigations the sodium salt of tetrabromophenolphthalein was used throughout. Details of the technique adopted were given, emphasis being laid on the necessity for slow injection of the dye and for the control of the patient as regards diet during the ensuing forty-eight hours. In most cases a slight reaction due to vasomotor shock was observed after the injection, but in no case was any serious symptom encountered. Radiographs of the gall bladder area were taken at four, eight, twenty-four, and thirty-six hours after the injection. The rationale of the method was explained and radiographs, illustrating the appearances in normal and pathological gall bladder conditions, were shown. Records of ten cases in which the gall bladder was investigated by this method and in which operations were subsequently performed were detailed; also of four cases which were not operated on. Of seven cases where a pathological condition of the gall bladder was found at operation, only one case had given the slightest x-ray evidence of this by the ordinary method, whilst all had given evidence of pathological changes when examined by Graham's method. Of two cases where a definitely normal gall bladder was found at operation, both had given definite indication of a normal gall bladder by Graham's method. In the remaining case a pathological gall bladder was deduced from the findings by Graham's method, but at operation no gross disease was found, a slight adhesion in the region of the neck of the gall bladder being the only abnormality present. This method was thus seen to be of definite value as a diagnostic aid in the examination of the gall bladder in those cases where by the ordinary direct method of radiography a negative finding was obtained; by no other means short of operation could it be ascertained whether a negative finding signified a normal condition of the gall bladder or not.

Mr. H. DE LISLE CRAWFORD described a rapid method of doing appendicostomy by a stab incision at the close of an abdominal operation, the purpose being to give large quantities of water and glucose for several days. The method was useful in emaciated or shocked patients where there was a danger of post-operative vomiting. He described also a new technique for permanent colostomy through a one-inch incision, by which a neat, well controlled opening

was obtained. The principle involved was that the colon was drawn out through an opening that barely admitted its passage, and that as a result the knuckle of bowel obtained was empty, stretched on its convexity, and could be immediately opened without soiling the wound.

### THE PSYCHOLOGY OF THE CRIMINAL.

At a meeting of the Medico-Legal Society on February 17th, Dr. NATHAN RAW in the chair; a paper was read by Dr. GODFREY CARTER entitled "The psychology of the criminal."

Dr. Carter remarked that a judge had recently observed to a grand jury that he wondered in many cases whether the cause was "uncontrollable impulse," or rather "impulse which ought to be controlled." Such a pronouncement from so high an authority made one realize afresh how complex was the problem of the mentality of the criminal. As a consequence of the war there had been let loose a primitive willingness to fight, to maim, or to kill, which, followed as it was by the mass butchery of the Russian revolution, had led directly to an aftermath of callousness and indifference to the sanctity of human life and morals which were alien to the spirit of our generation. Murders were being committed for causes which formerly would have evoked mild retribution only. As it was, the controlling centres of the brain were the first to give way under disease or stress, allowing the basic passions to reassert themselves and assume control easily. Much crime was only vicious and not the outcome of insanity as they knew it. Analysing the mental states of murderers in cases coming under his personal observation, he asked, Were they genuinely insane—the victims of irresponsible impulse as the result of disease of mind—or were they sane people whose criminal intentions ought to have been, and could have been, controlled? The legal defence of insanity was that the accused, at the time of committing the crime, was suffering from a defect of reason due to disease of mind, so that he did not know the nature and quality of his act, or, if he did know it, then he did not know that what he was doing was wrong. Dr. Carter pointed to cases where the impulse might become uncontrollable from temporarily emotional causes, yet the mind might be free from disease of an organic character, and he cited a case where the accused man told him he "seemed to see red," and so lost all control. This case would be found fairly typical of the majority—a wave of sudden passion, a failure to damp down a wrongful impulse, a reversion to the savage. Society must be protected, and unless overwhelming evidence of definite mental disease were produced there seemed no alternative but to rid the community of those who slew others whilst under impulses which ought to be kept in abeyance. Dr. Carter said he had observed it was almost impossible to secure a conviction for murder where the accused had once been an inmate of an asylum, and he did not consider this was altogether right. It had been said, no doubt with a good deal of truth, that no man was absolutely sane on all subjects at all times. Did they not all know of many most estimable people, level-headed members of society, who had at some time in their lives been subjected to the temporary seclusion of a "mental home," or who ought to have been so? Was this fact to grant immunity from the dread punishment of the law should they ever be indicted for murder? Rather than would he sympathize with those borderland people who just managed to keep outside the walls of detention, yet who were painfully aware of abnormal predisposition and thoughts, and had had to fight hard to keep to the road of approved conduct without falling into the ditch of insanity. He did not think definite insanity was often directly transmitted as such from parent to child, as was congenital idiocy. They knew that heredity was a potential disturbing factor, but nature was a still more powerful factor, working hard to restore mankind to the normal standard of mentality. He did not know that the interests of justice would be damaged if considerations of heredity were excluded altogether in judicial inquiries. For if it could be clearly shown that a man's parents, grandparents, and uncles and aunts, had all been insane, such evidence would afford no proof whatever that the man himself was insane.

As a matter of fact, did medical men often find certifiable people the children of similarly afflicted parents? Dr. Carter criticized the form of the verdict "Guilty, but insane," and asked how a person could be at the same time insane and guilty. If insane, the crime was merely a manifestation of the insanity. He referred to a case of infanticide where a mother, badly treated and half starved, had attempted to drown herself and her two children, but where she and one child had been saved. Such a verdict was returned, and the accused woman had been sent to a criminal lunatic asylum. This was a real case of uncontrollable impulse, not due to disease of mind, but to a temporary defect of reason, and he suggested that the verdict in such a case should be, "Not guilty of murder because suffering from temporary insanity at the time of committing the deed." Infanticide by the unmarried domestic class of woman was usually lightly punished, or the women were bound over under the care of philanthropists; it seemed to him that of the two, this class of case gained the most, for here the mother did not wish the child to live. Neither lawyers nor doctors appeared as yet to have reached a satisfactory definition of what constituted criminal responsibility. Some people were liable under great stress to suffer from defects of reason not due to disease of the mind, during which they lost the power of reasonable control over their actions, often with tragic results. Such cases were in a totally different category from those in which, either when "seeing red" or not, an individual put another to a violent death. Murder was the last thing which entered the distracted minds of these women. They decided at last that with so unbearable a lot hitherto, they would rather throw themselves on the mercy of God than on the compassion of mankind, and, in doing so, would take with them their helpless infants, whom by reason of their love they could not leave behind to face neglect and misery. When restored to considered reason a lifelong punishment awaited them in remorse. Was it necessary to brand them also as murderesses and consign them to associate with those of depraved mentality in the wards of a criminal lunatic asylum? The broad question to determine was: Was there a real uncontrollable impulse—a mental defect present which placed the culprit's action beyond his power of control? If it was a case of not exercising due powers of inhibition, control being really possessed by the individual, "impulse which ought to have been controlled" would be the right finding. He really did not consider that to the doctor evidence was of very much value except in cases of obvious delusional insanity of which he might observe indications. The medical evidence as to the mental condition of the accused was very contradictory and unsatisfactory, and he feared often trammelled the judge. The medical witnesses did their best, but he did not think they would ever be able to formulate in black and white an accurate definition of what constituted an insane impulse. He was not sure that the McNaghten definition, good as it was, could be used in every case, either by judge or medical expert, to decide directly the vexed question: "Was it an uncontrollable impulse or an impulse which ought to have been controlled?"

At a meeting of the Buxton Medical Research Society held on February 12th Dr. KNYVET GORDON read a paper on anaemia, with special reference to the clinical value of the examination of blood films. The paper was based on a combined clinical and haematological examination of 1,834 cases of anaemia, and was illustrated with lantern slides by a direct three-colour process and drawings of the different types of blood cell. The speaker emphasized the importance in diagnosis of first excluding the leukaemic group and then the other primary anaemias—namely, pernicious anaemia, and Banti's disease with its allies. The conclusion was drawn that pernicious anaemia was a congenital disease, and that haemolysis was not commonly a cause. Stress was laid on the value of the blood film in distinguishing in secondary anaemias between bacillary and coecal infections, and as a guide to a suitable vaccine in the treatment of the condition. Bacterial infection was described as the cause of the great majority of the cases of secondary anaemia, and the methods of discovering and dealing with the focus were discussed. Details were given of the technique of vaccine therapy, including laboratory tests for pathogenicity of the organisms isolated.

## Rebicus.

### DIGITALIS.

PROFESSOR A. R. CUSHNY in his monograph *The Action and Uses in Medicine of Digitalis and its Allies*<sup>1</sup> gives a clear and critical account, which will be of the very greatest value to the profession, of the present state of knowledge regarding the mode of action of these important drugs.

The book commences with a short summary of the conflicting evidence concerning the nature and number of the active principles present in digitalis. The author suggests that many of the substances that have been given distinctive names are really mixtures of two or more glucosides.

Considerable space is devoted to a consideration of the mode of action of digitalis on the frog's heart. The account is of particular value since it is critical, for the work on this subject is very uneven in quality. The author remarks in one place, "These experiments are chiefly of interest in suggesting that there are limits beyond which the much-enduring frog's heart is unable to beat." He is at pains to distinguish carefully between valid and worthless experiments, and thus is able to give a clear and coherent account of the important fundamental facts that have been ascertained from experiments on the frog.

The evidence derived from mammalian experiments is next considered, and here also the author distinguishes carefully between effects produced by the drugs in therapeutic doses and those which are only to be observed when several multiples of a lethal dose are administered. The experimental section occupies nearly two-thirds of the volume, but the author points out that during the whole nineteenth century our knowledge regarding the therapeutic action of digitalis was at a standstill and that the rapid progress of the last fifteen years has been dependent on the accurate analysis of the mode of action of digitalis, which was gained by animal experiments. As regards the therapeutic use of digitalis, chief attention is devoted to its effects in cases of auricular fibrillation, and a very clear account of this action is given. A cautious attitude is adopted towards the vexed question of the benefit produced by digitalis in heart disease without disorder of rhythm; the conclusion (p. 237) is:

"There is no doubt of the benefit attending the use of digitalis in some of these cases, whilst there is as little question that in others the treatment is valueless; and at present it is not possible to differentiate between these."

The question of the value of digitalis in the treatment of pneumonia is also discussed, and the author concludes that—

"The routine treatment of pneumonia with digitalis is therefore not established as advisable, and the general view is that it should not be given until some special indication is presented."

An interesting account is given of the toxic effects of digitalis, and details are given of the experiment Koppe made on himself. It is particularly interesting, because Koppe took a milligram of digitoxin by mouth without any certain toxic effects, but a dose of 2 milligrams taken four days later nearly produced a fatal result. This shows the unpleasantly narrow margin between the therapeutic and the toxic dose of digitalis.

The final chapter in the book deals with the mode of administration of digitalis and its allies, and details are given of the various intensive methods of treatment that have been introduced in America.

Regarding the choice of preparation, Professor Cushny makes some interesting criticisms of the innumerable proprietary preparations that have been introduced as alternatives to digitalis. He points out that the claim so frequently made that a particular digitalis preparation does not produce cumulative action or nausea must of necessity be unfounded, since any digitalis preparation which does not produce these effects must either be inert or else so weak as to be valueless. He concludes (p. 264):

"These proprietary preparations are often carefully prepared, standardized, and put on the market in attractive forms, so that some of them have been widely used; but none of them is superior

to a carefully standardized pharmacopoeial preparation, and all are sold at extravagant prices. In some instances the strength has been found to vary widely, and this is a source of danger."

Professor Cushny has devoted many years of his life to the study of the action of digitalis, and we are indebted to him for much of our present knowledge of this subject. His volume may with reason be considered a masterpiece of its kind, since all aspects of the subject are considered and all are subjected to a shrewd critical judgement based on the author's wide first-hand knowledge of the problems involved.

### SUNLIGHT AND ULTRA-VIOLET RAYS.

THE healing powers of natural and artificial sunlight are exciting wide-spread interest at the present time in view of the work of Dr. Rollier in Switzerland and Sir Ilar, Gauvain and Dr. Leonard Hill in this country, and the new books on ultra-violet ray therapy here reviewed will probably be welcomed by medical men looking for a concise description of the way to use the various apparatuses which generate ultra-violet rays, and what may be expected from them. Dr. FRANCIS HOWARD HUMPHRIS's book is entitled *Artificial Sunlight and its Therapeutic Uses*. It has been written for medical practitioners. The author does not forget that many years have probably elapsed since such readers studied physics, and he explains the scientific basis of light therapy in a clear and simple way. He has a brief chapter—perhaps a little too brief—on apparatus used for generating ultra-violet rays, and the remaining two-thirds of the book are devoted to description of the treatment of disease. Here the different maladies for which light treatment is beneficial are discussed in turn, with a recommendation as to which particular form of apparatus is most suitable for each. The book is set up in an attractive way, and will prove useful to those seeking special information on this subject. Of more general interest is the author's contradiction of the claims of many "ultra-violet ray apparatuses" as used in the "beauty parlours" (p. 25) and his reference to the proposed institution of sun baths in Ken Wood, adjoining Hampstead Heath. Many quotations are scattered throughout the earlier chapters, to which, for the most part, Dr. Humphris attaches no references, only giving the name of the author. Quotations are often an ornament to a book, and to attach references to such as are borrowed from well known or illustrious writers is sometimes unnecessary and might be pedantic; but passages are cited in this book the exact origin of which many readers may wish to know; such a one appears on page 26. Being curious as to the source of certain quotations, we took the trouble to trace one imputed to Dr. Rollier (without chapter or verse) which is made rather much of on page 28:

"Sun and ultra-violet rays bear much the same relation to one another as crude drugs do to their synthetically prepared chemical substitutes."

We found these words eventually in Dr. Rollier's book *Heliotherapy*, but in the section of this book written by Dr. Amstad, the surgeon at Rollier's institution at Leysin. This, therefore, is Amstad's opinion and not Rollier's. A reading of the context makes it questionable whether Dr. Humphris has put this remark to a use with which Amstad would agree. A less important point in terminology arises when Dr. Humphris speaks of ultra-violet rays as antigenic.

"In brief, ultra-violet rays assist the development of antibodies. They are therefore antigenic and capable of destroying bacteria within the body" (p. 51).

The term "antigen" is commonly limited to any substance which, when inoculated into the body, is capable of causing the production of antibodies. Radiation may result in the development of some antigen within the tissues, though whether it acts in this way and what the hypothetical substance is remains undetermined. We should not speak of a holiday at the seaside as an antigen, or even as acting antigenically.

<sup>2</sup> *Artificial Sunlight and its Therapeutic Uses*. By Francis Howard Humphris, M.D. Brux., F.R.C.P. Edin., L.R.C.P., M.R.C.S. London: H. K. Mulford, Oxford University Press. 1924. (Demy 8vo, pp. xiv + 170; 12 figures. 8s. 6d. net.)

<sup>1</sup> *The Action and Uses in Medicine of Digitalis and its Allies*. By A. R. Cushny, M.A., M.D., LL.D., F.R.S. London: Longmans, Green and Co. 1925. (Med. 8vo, pp. xi + 303; 77 figures. 16s. net.)

To Dr. PERCY HALL's book *Ultra-Violet Rays in the Treatment and Cure of Disease*<sup>3</sup> both Sir HENRY GAUVAIN and Dr. LEONARD HILL have written introductions. Dr. Hall addresses himself not only to medical men, but also to educated members of the laity, particularly such, he observes, as are public-spirited citizens and interested in the health and welfare of the poorer members of the community. The book has been written to encourage the establishment of light departments in hospitals and light clinics in big centres of population. The earlier chapters, on the history of light therapy, the value of sunlight, heliotherapy, artificial light, and ultra-violet radiation, provide interesting reading for everybody. After reviewing the different sources of ultra-violet light, Dr. Hall concludes that the tungsten arc lamp is the handiest and generally most serviceable:

"In effecting a final choice as to the source of ultra-violet radiation to be employed, one can safely decide upon the tungsten arc as being of the widest utility, and of yielding a spectrum which is the richest in amount and variety of ultra-violet emanations."

He mentions, but does not give much detail about, the Finzen lamp, mercury vapour lamp, and other appliances. The remainder of the book discusses the value of ultra-violet radiation in skin diseases, rheumatic disorders, neurasthenia, pulmonary tuberculosis, and catarrhal conditions of the respiratory tract and various other diseases. The whole book can be read from cover to cover in about two hours without any break of interest. Both classes to whom it is addressed will find it an instructive introduction to ultra-violet ray therapy.

#### INFLAMMATION OF BONES AND JOINTS.

IN the textbooks of a generation ago much space was devoted to the subject of inflammation of bone, yet it is probably true that the student was more often puzzled than informed, and landed in an obscurity from which he rarely emerged. The obscurity still exists to some extent and in some quarters, and the virtue of Professor ELY's book on *Inflammation in Bones and Joints*<sup>4</sup> is that it discards the old notions of "rheumatic osteitis" and "sclerosing osteitis" regarded as entities, and starts afresh on a more rational basis. The changes which occur in the bone tissue itself are probably of a purely passive kind, consisting of absorption or atrophy, production or hypertrophy, and death or necrosis, and they result from the more important and essential changes in the contained marrow. The old distinction between osteitis and osteomyelitis, therefore, has probably no foundation in fact, and there is much to be said in favour of the custom of some recent writers who discard the terms "osteitis" and "periosteitis" altogether, the essential lesion in these processes being a myelitis or osteomyelitis. A similar confusion of ideas was prevalent with regard to the term "arthritis," which was applied not only to lesions strictly confined to the joint, but also to conditions in which the disease was chiefly and primarily a marrow lesion. The term should, as the author points out, be restricted to lesions of the synovial membrane, arthritis and synovitis being regarded as synonymous terms.

The practical application of these views to the group of diseases under consideration greatly simplifies our conceptions, since the two essential lesions involved are clearly distinguished. These terms adequately define the lesions when they occur singly, and it might be supposed that some such term as "myelo-synovitis" would be appropriate for the combined lesions. Professor Ely has, however, hesitated to push his views to their logical conclusion; he states that

"the custom is almost universal to describe the chronic arthritides as separate from inflammation in the shafts. This custom has decided merit, for, when the joint is involved, the symptoms of the arthritis usually dominate the picture. Most arthritides are, however, the result of a previously existing myelitis."

<sup>3</sup> *Ultra-Violet Rays in the Treatment and Cure of Disease*. By Percy Hall, M.R.C.S.Eng., L.R.C.P.Lond. With introductions by Sir Henry Gauvain, M.A., M.D., M.C.Camb., and Leonard E. Hill, M.B.Lond., F.R.S. London: William Heinemann, Ltd. 1924. (Demy 8vo, pp. xvi + 110; 20 plates, 7s. 6d. net.)

<sup>4</sup> *Inflammation in Bones and Joints*. By L. W. Ely, M.D. Philadelphia and London: J. B. Lippincott Company. 1923. (Med. 8vo, pp. 433; 144 figures; 30s. net.)

Hence an incorrect nomenclature is deliberately adopted, in deference to custom. He regards the red marrow of bone as being analogous to lymphoid tissue, and, like it, peculiarly subject to tuberculous infection—a view that goes far to explain both the frequency of its infection and the local incidence of the disease within the bones. Further use is made of the analogy in explaining the beneficial effects of rest and ankylosis on the tuberculous process. In the bones of a joint which has been put out of function by immobilization there occurs a reduction of the lymphoid marrow, which is thus rendered less favourable for the growth of the bacilli. A similar reduction, and even a complete conversion into fatty marrow, has been described by Ollier and Maclaure as occurring after bony ankylosis, the synovial membrane disappearing and the bone ends assuming more or less the internal structure of the shaft.

From principles based on these views and on the opinion that tuberculosis of the joints is in itself a comparatively harmless disease, and only becomes serious when a secondary infection is added, the author deduces the general lines of treatment to be adopted. For children he advocates conservative treatment in all cases, while for adults he considers that it should be practically always radical, the object being to cause permanent destruction of the joint, rendering it an unsuitable habitation for the bacillus. Professor Ely's work is marked by original and independent thought, and is a valuable contribution to the pathology of the subject.

#### EXPERIENCES IN SURGERY.

WE have already had occasion to mention a book on practical surgery written by M. VICTOR PAUCHET, and issued in parts. We formed a favourable opinion of it, and are therefore not surprised to find that the book has been translated by Dr. F. R. B. ATKINSON and issued, with a general introduction by Sir CHARLES GORDON-WATSON, in four volumes with the title *Practical Surgery Illustrated*.<sup>5</sup> It is a personal production and does not claim to be a textbook of surgery. The author's method is to illustrate each step of an operation by drawings taken from nature by M. S. du Pret, who made the illustrations for Testut's *Anatomy*.

For the treatment of inguinal hernia he suggests what he calls the "endo-peritoneal method." He opens the peritoneum above the sac and inserts a finger into the sac from within, pulls the structures of the cord off the sac, and invaginates it and brings it through the opening in the peritoneum. In this way there is, he says, very little disturbance of the cord; a portion of the rectus sheath is used to cover it. In appendix abscess he cleans out the abscess cavity with ether and does not search for the appendix. In perforated appendix he believes in multiple drainage. In quiescent appendix he considers invagination of the stump unnecessary. For ventral hernia he employs bronze wire suture for all the structures outside the peritoneum. These are twisted over gauze pads after the skin has been approximated by Michel's clips.

Adenoma of the breast is treated by submammary incision, and the illustrations are so clear as almost to render the text superfluous.

Local or sacral anaesthesia is employed for pile operations. In the ligature method he sutures the pile stumps to the skin. He has a good deal to say about carcinoma of the rectum; his conclusion is that of "four cases applying for treatment, one will be inoperable, two will be operable by the two-stage perineal method, and one by the abdomino-perineal method." The latter he describes fully with the help of excellent illustrations. On the subject of intestinal stasis he is an enthusiastic apostle of Lane. Kinks and bands are fully illustrated, as are the operations for treating them. Gastrectomy is advocated for gastric and pyloric ulcers, and also for jejunal ulcers. Though other methods are also discussed, gastro-enterostomy is not advised in cases of perforated ulcer unless pyloric stenosis is present. In cancer

<sup>5</sup> *Practical Surgery Illustrated*. By Victor Pauchet. Translated by F. R. B. Atkinson, M.D., C.M. Edin. Univ. With an introduction by Sir Charles Gordon-Watson, C.M.G., F.R.C.S. Vols. I to IV. London: E. Benn, Ltd. 1924. (6½ x 11: Vol. I, pp. xiii + 293, 217 figures; Vol. II, pp. ix + 252, 199 figures; Vol. III, pp. x + 248, 368 figures; Vol. IV, pp. xi + 255, 207 figures. 18s. 6d. per volume.)

of the cervix radium is employed before operation. For carcinoma of the stomach total gastrectomy with jejuno-jejunostomy is described, and the en-Y operation for duodenal ulcer is preferred. In performing colectomy for cancer of the rectum the author brings the colon through the rectus with a half-twist in the hope of obtaining sphincteric control. In the two-stage operation he performs colectomy, inserts radium, and a month later completes the perineal excision.

In Volumes III and IV the author continues in the same strain, and in some places amplifies subjects previously dealt with. In posterior rhizotomy he turns up the spinous processes as a bony flap, opens up the laminae with gouge forceps, and replaces the flap to prevent deformity. The remarks he has to make on the operative treatment of fractures are illustrated by an account of the use of steel bands, devised by Professor Putti, which encircle the bone. On the subject of cancer of the tongue Pauchet is very dogmatic; every lesion not proved innocent should, he says, be treated as malignant, and he regards improvement from antisyphilitic treatment as a dangerous illusion. When the front of the tongue is involved the buccal route is advised, when the posterior half is affected the submaxillary; the jaw is split when the floor of the mouth is encroached upon. The external carotid is invariably tied when the glands are removed.

In gastric ulcer he advocates partial gastrectomy, and has devised a special clamp for this purpose. For duodenal ulcers posterior short-loop gastro-enterostomy is advised, and when the acidity is high, partial gastrectomy. He states that 5 per cent. develop jejunal ulcers, that 25 per cent. are partial cures, and 70 per cent. cures. He believes that the symptoms are due to cholecystitis, appendicitis, or intestinal stasis. When discussing recurring dislocation of the shoulder he advises excision of the redundant capsulo and suture of the overlapped margins; the incision is along the mid-axillary line and the approach along the neurovascular bundle, which is retracted forwards. Pauchet holds strong views on the formation of gall stones and their relation to the pancreas. He believes that the gall bladder is infected by way of the portal vein, the *Bacillus coli* being eliminated by the liver into the bile; he thinks also that all stones are formed in the gall bladder, which he regards as a mechanical shunt for the bile when the ampulla of Vater becomes blocked, and that in this way it prevents pancreatitis. He does not believe in medical treatment for gall stones, and prefers cholecystectomy to cholecystostomy.

In an opening chapter he describes how a surgical clinic can be established in a provincial centre.

### NOTES ON BOOKS.

ALTHOUGH the number of pages in the thirty-fifth edition of *Burdett's Hospitals and Charities*<sup>1</sup> is approximately the same as in the last edition, it contains considerably more information, the size of the page having been increased both in length and width. The statistical tables benefit to a large extent by this change—a most important point, since this year book of the British Empire in respect of hospitals and kindred charities. The various financial details and summaries are set out more clearly than has been hitherto possible. Among important subsections added for the first time is one devoted to holiday homes and homes of rest, which will be found under the heading "Convalescent Homes." This list enables a distinction to be made between those homes which provide for patients in need of rest and change of air and others for persons recovering from serious illness; the addition will be found valuable. A list has been made of all the hospitals throughout the world where accommodation is reserved exclusively or specially for British seamen. A new sub-section has been added to the section dealing with missionary description of London, provincial, and Scottish settlements for social work. Under the heading of "Africa" the Gambia hospitals, the hospitals in T and those in Uganda have now separate sections. It is interesting to note that the account of hospitals of South-west Africa has been increased from a single sentence in the last issue to thirteen entries in the present, whilst the lists of hospitals in other parts of Africa have also been greatly

enlarged. The considerable progress made lately in contributory schemes receives recognition. The great advance by King Edward's Hospital Fund for London is recorded, and tables are supplied giving the analysis of the receipts and expenditures of this fund and of the League of Mercy since their inception. The directory of London and provincial hospitals, universities, and other institutions has been brought up to date, and the present issue represents a decided advance in value and interest, even over the high standard of its predecessors.

The third edition of *Diseases of Women*,<sup>2</sup> by Ten Teachers, has been issued under the general editorial direction of COMYNS BERKELEY, H. RUSSELL ANDREWS, and J. S. FAIRBAIRN. This valuable book has made a place for itself and little need be said in regard to the present edition, which contains only minor alterations and improvements. The size of the book has not been increased, and we venture to express the hope that in subsequent editions it will not be allowed to grow in bulk. We congratulate the publishers on having reduced the price—a rare phenomenon in these days. The teaching, both from the pathological and clinical sides, represents the authoritative opinion of British gynaecologists in general; the section on operative technique is clearly written and clearly illustrated, and should suffice for the needs of students and practitioners and all save those who are making a specialty of gynaecology.

The monograph on *Josef Skoda*<sup>3</sup> by Professor MAXIMILIAN STERNBERG, which forms the sixth volume of a series of biographies edited by Dr. Max Neuburger, contains a full account of Skoda's activities as pathologist, writer, and lecturer, and a sketch of contemporary medical life in Vienna. Apart from his work on auscultation and percussion for which he is chiefly remembered, Skoda took an active interest in practical hygiene and wrote on such subjects as the macadamizing of roads in the new city park, compulsory vaccination, and especially the water supply of Vienna. A report made by him on medical education contained several new ideas which were not realized until many years later, particularly as regards the creation of an Institute for experimental medicine. In spite of his scepticism in therapeutics Skoda had a large consulting practice, which increased still more when he gave up his hospital work and was able to devote himself entirely to his private patients. In private life Skoda does not appear to have been altogether the top-heavy and somewhat inhuman old bachelor described by Garrison; he was generous to the poor, and he deserves special credit for championing the cause of Semmelweis. A bibliography of Skoda's writings and of works written under his influence is given.

A new quarterly medical periodical has appeared with the title of the *British Journal of Venereal Diseases*. It is edited by Lieut.-Colonel L. W. HARRISON and Dr. E. R. T. CLARKSON, and published under the direction of the Council of the Medical Society for the Study of Venereal Diseases. Sir Humphry Rolleston, in an introduction to the first number (January, 1925), remarks on the need for intensive study in attempting any real advance in knowledge, owing to the complexity of modern medicine; he adds that the study of venereal disease deserves to be considered, and has indeed become a legitimate specialty. The existence of venereal disease departments at the hospitals and of venereal clinics in connexion with the Ministry of Health is held fully to justify the appearance of a special journal. It is proposed to cover the whole subject of venereal disease, apart from the important, but thorny, problem of moral considerations. Original articles and critical reviews of recent knowledge will be published, summarizing the most recent research and appealing to general practitioners as well as venereal specialists. Colonel Harrison contributes to the January issue an article on the public health services and venereal diseases; Dr. E. P. Cumberbatch and Dr. C. A. Robinson discuss the use of diathermy in cases of gonococcal infection; Dr. W. J. Tulloch contributes notes on the complement fixation reaction in gonorrhoea; Dr. E. T. Burke considers the administration of bismuth in syphilis; Dr. Svend Lomholt of Copenhagen deals with the pharmacology of bismuth, with reference to its therapeutical employment in syphilis; Dr. R. N. Ironside describes the treatment of general paralysis by malarial inoculation; and Dr. H. C. Semon considers in detail skin affections commonly mistaken for syphilis. There would appear to be a need for such a journal, and the high standard of its first number should commend it very widely.

<sup>1</sup> *Diseases of Women*. By Ten Teachers. Edited by Comyns Berkeley, H. Russell Andrews, and J. S. Fairbairn. Third edition. London: Edward Arnold and Co. 1924. (Med. 8vo, pp. xi + 641; 215 figures. 25s. net.)

<sup>2</sup> *Josef Skoda*. By Maximilian Sternberg. Vienna: Julius Springer. 1924. (5 1/2 x 8 1/2, pp. 92; 1 plate.)

SATURDAY, FEBRUARY 28TH, 1925.

## SIR CLIFFORD ALLBUTT.

It is too soon yet to attempt to write what the eighteenth century would have called "a character" of Sir Clifford Allbutt. We are too near to him; we feel too vividly the presence of that slight, alert figure, the mobile face, with eyes looking, not through you, but into your mind; often, when seated, leaning forward in his eagerness to grasp the proposition that was being put before him, for he was by no means a man to take anything for granted. Though always kindly and generous, his mind was of the critical cast, and one could watch him turning over for a moment or two what had been put to him in conversation. Sometimes he would reach a judgement quickly and would agree, perhaps with a reservation; sometimes he would quite frankly disagree; and sometimes, after a rather longer pause, he would say, "I am not sure about that, and would like to think it over." It was a great compliment to the younger or lesser men, who could always be quite sure that the idea was not rejected or judgement about it suspended merely because it was new. It was part of the alertness of his mind to be ready always to examine new ideas and to accept the teaching of new facts, but he was not in the least dazzled by newness. His critical faculty awoke at once, and he applied it to his own work or his own theories as readily as to those of others.

As a physician he will probably be remembered for his work on the circulation—the heart, the aorta, and blood pressure. What he did as a young man about the optic disc in relation to general diseases was perhaps even more original, but the whole neurological and ophthalmological world descended upon this new method, and in it his reputation is that of a pioneer. About angina pectoris, heart strain or stress, and high blood pressure it was different; these are still matters of keen dispute; they were in his mind throughout the whole of the second half of his life, and one of his latest public utterances was the speech he made last May after the lecture at the Royal College of Physicians of London in which Professor Wenckebach of Vienna gave his reasons for adhering to Allbutt's original doctrine that angina pectoris was related to the condition of the aorta. He would, we feel pretty sure, have agreed that medicine was a science, with its own data and its own methods. He kept himself well acquainted with the advances of physiology, and made free use of them in his writings and addresses, but as sidelights. He based himself on bedside observation confirmed or corrected by pathology.

Allbutt was very human. Many as were his distinctions, great as he must have known his reputation to be, there was never the smallest trace of pomposity. He was ever the friend of the general practitioner, whose qualities, trials, and difficulties he got to know well during his time in Leeds, when he journeyed far and wide in West Yorkshire, into its teeming industrial towns and into its rugged valleys, where in a harsh climate a hardy peasantry wrings a living from an unkindly soil. He was therefore, in this respect as in every other, well qualified to be President of the British Medical Association. About this all that

need be said is well said by Dr. Brackenbury in the few moving sentences he has contributed to our biographical notice. Allbutt was a scholar and never let his knowledge of Greek and Latin writers rust. Of this his book on *Greek Medicine in Rome*, published in 1921, is sufficient evidence, but his interest in science was lively and continuous. In this he was like the great men of the later renaissance. He was a great physician and a very perfect gentleman.

## THE SYMPATHETIC INNERVATION OF STRIATED MUSCLE.

It is fortunate that Professor Elliot Smith was willing to undertake the preparation, delivery, and publication of the lectures to have been given by the late Professor J. I. Hunter, the tragedy of whose death we must lament the more as we read of the far-reaching influences of his brief life of research. Professor Elliot Smith has not only marshalled in orderly sequence all the numerous aspects of Hunter's investigations which shed light upon his fundamental thesis with regard to the sympathetic innervation of skeletal muscle, but has indicated the wide effects of these researches upon neurology, and has suggested how they will probably harmonize many views which hitherto have appeared to be discordant.

The careful investigations of Professor Kulchitsky, whose death we regretfully reported only a fortnight ago, suggested the earlier experiments which led to the discoveries reported in the lectures. Kulchitsky demonstrated in 1922 that medullated and non-medullated nerve fibres never terminate in the same muscle fibre. Hunter and his co-workers have confirmed this, and overwhelming evidence has been advanced from various sources in support of the belief that there are two kinds of skeletal muscle—the one innervated by somatic medullated nerves, and the other supplied by non-medullated sympathetic fibres. The experimental and clinical evidence demonstrating the different and distinct functions of the two kinds of striated muscle is equally convincing. In addition to the knowledge of the important effects of sympathetic denervation upon the spinal and decerebrate animal, which was conveyed in recent papers by Hunter and Royle, we are now presented with a lucid account of the most illuminating experiments upon birds. For anatomical reasons, which are set out in the lectures, the bird's wing offers a unique opportunity for studying the postural activity of voluntary muscle, and for determining the influence of the somatic and sympathetic nervous supply individually. These experiments, and particularly those in which "contractile" and "plastic" tone were dissociated so clearly, must dispel any doubt or uncertainty which previously existed in the minds of people who were only aware of the earlier experiments. The accurate descriptions of the results of these experiments cause the essential and distinguishing characteristics of contractile and plastic tone to stand out in bold relief, and demonstrate how so many previous workers in this field have been misled by an obsession regarding the contractile element of tone.

The researches of Hunter and his co-workers will do much to eradicate widespread misconceptions about tone, and will assist a larger proportion of the profession to appreciate the real significance of the fundamental doctrines arising out of the discoveries of Sherrington. It is absolutely essential for every surgeon to have a clear vision of the two elements of

tone which are together responsible for the production and maintenance of posture before he can attempt to investigate a patient suffering from muscular rigidity. Unless he has a correct conception of the meaning of contractile and plastic tone, it is impossible for him to determine the cause for the rigidity and decide whether there is an excess of one or the other or both elements. Both the experimental and clinical evidence prove—and this must be insisted upon most emphatically—that sympathetic ramisection can only have any beneficial effect when there is an excess of plastic tone. It has been demonstrated that posture alone is not an indication for sympathetic ramisection, and that posture may be misleading. On the other hand, the presence of the "lengthening and shortening reactions" of Sherrington, and the slowness in execution of the tendon reflexes, are important indications for the operation; it will, of course, be understood that benefit can only be expected in patients who retain considerable voluntary power, much of which may be hampered seriously by the increased plastic tone. Failure to determine the presence of an excess of plastic tone and voluntary control must inevitably lead to disappointing results, and may thus bring unfair discredit upon this valuable work. It is probable that this may threaten the progress and future development of this work more than the risks of failure from faulty technique and neglect to cut the appropriate sympathetic rami, since the latter is a straightforward anatomical and surgical problem, whereas the former demands very considerable neurological experience, training, and foresight. Quite formidable difficulties are to be encountered in both cervical and lumbar ramisection, but Royle has presented a very complete account of both operations, and has devised several advantageous manœuvres to surmount the most serious difficulties.

It has been found that even in the most suitable patients the effect of the ramisection upon plastic tone is quite frequently not manifested to any extent until some days or even weeks after the operation. Allusions are made to comparable conditions in some of the experiments, and in this connexion it is of considerable interest to remember that the most striking effect upon decerebrate rigidity was in that case where the longest interval had intervened between sympathetic denervation and the decerebration. It is not easy to see why the "fixing" fibres should slowly lose this characteristic function, and Hunter and his co-workers have as yet been unable to advance an adequate explanation for it. The analogy with smooth muscle is a fascinating suggestion, but, as is stated in the lectures, there are some very serious objections to it. It is one of the several problems which are being vigorously investigated further, and it is possible that its solution may add further knowledge of considerable importance. The delay in the effect of the operation upon plastic tone, and the persistence of the effects for long periods after ramisection in cases recorded by Royle, refute the suggestion that the beneficial results are solely due to vaso-dilatation, since the vasomotor changes are most marked immediately after sympathetic denervation and diminish or disappear later. The investigations which have been carried out to determine the reflex arcs concerned in maintaining the two elements of tone will be studied with the utmost interest. It is to be hoped that the publication of these researches upon the control of tone by the brain will in particular stimulate clinical and experimental investigation, so that this most brilliant work inspired by Hunter may be developed further and completed—it is a duty we owe to his memory.

## ON GALL STONES AND ON ACIDOSIS.

MANY points of great interest are raised by Sir Berkeley Moynihan in the thoughtful and informing address with which this issue opens. No one has done more than he to elucidate the problems which gall-bladder pathology has set us, and in his present paper he is able to advance a little further. He has always been an upholder of the theory of cholecystitis as an entity, regarding gall stones as a necessary corollary of the later stages of the disease. That a gall stone cannot come into being in a moment is, of course, sufficiently obvious. Our knowledge of its precise method of development is still most incomplete, but that a period of profound change in the gall-bladder wall must precede the formation of a stone is certain. It is also certain that this diseased gall bladder may often give rise to symptoms before stones are present—that "acalculous cholecystitis" is a definite entity, and should be treated by removal of the offending organ. Yet there are many surgeons who, having opened the abdomen in the confident expectation of finding gall stones, and, being disappointed, retreat with perhaps a prophylactic appendectomy as a sort of rearguard action. In spite of a most clear clinical history of biliary trouble, they feel that they have been mistaken in their diagnosis when no stones are found. Much depends in these cases on the appearance of the gall bladder, for the changes occurring when disease processes exist are now well known. It is noteworthy that a sterile culture made from aspirated bile (whether at operation by needle puncture or by the duodenal tube beforehand) is not an absolute criterion of normality. Sir Berkeley gives some statistics of the results of cultures taken from the different parts of the gall-bladder wall. These would have been even more instructive had some figures been added relative to the finding of stones in these cases and the bacteriology of their contents. They show, however, that *Bacillus coli* is the commonest infecting agent. The interest of this observation lies, as the author points out, in the frequency of gall stones in women on the one hand, and their proneness to urinary infections with this organism on the other. It would be interesting to know whether the colon bacillus produces an increase in the cholesterol content of the blood. Such an increase is known to occur in infections by *B. typhosus*.

This leads us to a portion of the address which is of outstanding importance—namely, the estimations of blood cholesterol which have been carried out at Leeds. In 65 per cent. of gall-bladder cases hypercholesterolaemia was found, whilst in another 23 per cent. the figure was "high normal." The reverse findings were no less important, for a low figure (below 0.133 per cent.) was present in only 2 per cent. of the gall-bladder cases, whilst such a reading was not uncommon in cases of gastric and duodenal ulcer. These results seem to us to mark another milestone on our way to a complete understanding of gall-stone pathology. For it is known that the blood cholesterol concentration rises in pregnancy and during menstruation. It is also known that cultures of the colon bacillus will precipitate cholesterol from the bile *in vitro*. It appears that we are within a measurable distance of being able to piece together the story of gall stones.

Other points of importance are raised in the course of the paper. Of these the most urgent for note at the moment is the section on the treatment of acidosis or ketosis. Sir Berkeley pays tribute to Dr. Thalheimer of Milwaukee, who apparently first tried the simul-

taneous injection of glucose and insulin as a remedial measure for this distressing post-operative malady. Dr. Lillian Farrar of the New York Women's Hospital had published (in 1921) an account of the value of intravenous injection of gum-saline-glucose in preventing and combating ketosis, particularly after long operations. She showed that the range of combining power of carbon dioxide in the blood of women is less than that of men, the danger point being thus sooner reached; this no doubt accounts for the greater tendency of the female to develop ketosis. But it has been found that to run glucose into the veins may not be enough. Dr. Thalhimier's first case was one in which supravaginal hysterectomy had been performed for fibroids; ketosis developed, and 500 c.cm. of 5 per cent. glucose was administered intravenously without effect; 600 c.cm. of the same solution was then given together with 10 units of insulin, and the picture was entirely altered; within a period measured in hours the danger mark had been passed. Most surgeons give glucose by rectum after severe operations, but its absorption by the bowel is uncertain. In a child at least it is often insufficient to prevent the appearance of diacetic acid in the urine, and when such cases recover, as they often do, it may well be that the rectal glucose has really had little influence. Subcutaneously glucose is irritating, and cannot be given in the large amounts necessary without fear of sloughing. On the other hand, it is not easy to sterilize, though fortunately the blood is usually well able to look after itself. In the combined use of glucose and insulin we seem to have a method of treating acidosis more hopeful than any which has gone before, though experience is needed to standardize its application.

## THE EVIDENCE TO THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.

The draft Memorandum of Evidence proposed to be given by the British Medical Association before the Royal Commission on National Health Insurance, which appeared in the SUPPLEMENT of January 3rd, has been considered by local meetings of the profession throughout the length and breadth of Great Britain. The views of some 200 such meetings upon the questions submitted with respect to the more important matters dealt with in the Memorandum have been considered by a joint meeting of the Insurance Acts and Royal Commission Committees of the Association on February 5th, and by the Council on February 18th. In effect the views of the local meetings show general agreement with the draft Memorandum of Evidence, and the amendments made by the Council, after considering the various opinions expressed, are designed to give emphasis and do not in the main involve any alterations of substance. The Memorandum as revised is printed in this week's SUPPLEMENT.

For the assistance of readers we propose to summarize quite shortly the general purport of the revised document as it now stands for final consideration before it is submitted to the Royal Commission on behalf of the Association. This summary must not be taken as in any way official. It is intended to serve only as a guide to one who has not yet read the document with the attention its importance demands. We shall then indicate for purposes of comparison the principal changes that have been made.

After the preamble in Part I, it is declared in the early paragraphs of Part II that a National Insurance scheme is not necessarily the best means of promoting

the national health, for no fewer than seven other possibilities would be likely to produce even more satisfactory results; that once a National Health Insurance scheme is decided upon it should have regard to the maintenance of health and prevention of disease, and not merely be concerned with the alleviation or cure of morbid conditions after they have arisen, and that consequently the existing machinery and medical personnel of the public health service should be brought into closest possible touch with the scheme; and that the measure of success which has attended the experiment of the provision of medical benefit under the National Health Insurance Acts has by general agreement sufficed to justify the profession uniting to ensure the continuance and improvement of an insurance system. At this point the advantages and disadvantages of the present insurance system are set out. The five fundamental principles of any National Health Insurance scheme are stated. Next follows a section on the persons to be provided for. In the next section, on the extent of the provision to be made, the Memorandum urges that, besides the general practitioner service, there should be complete arrangements for consultant and specialist advice and treatment, full laboratory facilities for clinical purposes, residential institutional treatment so far as compatible with present limited accommodation, dental advice and treatment, such ancillary help as can be given by nurses and masseurs, and an ambulance service—all equally available to every insured person. These additional services should as a rule be available only upon the recommendation of the insured person's general practitioner. It is urged further that, besides a cash maternity benefit, there ought to be a complete maternity service for insured women and for the wives of insured men, comprising medical examination (not compulsory, of course) and supervision during pregnancy, attendance by a midwife during normal labour and the puerperal period, and attendance by the practitioner of choice when necessary during the puerperal period and pregnancy, with access to a consultant and specialist service.

The next section deals with Regulations and Terms of Service. It opens with a declaration that the free choice of doctor now obtaining provides facilities for abolishing all minor complaints by insured person or practitioner. It urges that the insured person should be required to choose his doctor before illness arises and to prove his title to benefit or be liable to a penalty or the payment of a fee; the practitioner on his side being subject to penalty if he wilfully charges a fee for any service within his contract or if his general conduct is detrimental to the interests of the service. It holds that a practitioner should not be liable to complaint for any honestly made statements in records or reports or certificates, but that refusal to keep records or make reports or furnish certificates on proper occasions, and wilful false statements, should lay him open to serious official action. It urges that all complaints against a practitioner should be sent in the first instance to the chairman of the Local Medical Committee and the chief administrative medical officer of the local authority, and that an effort should be made to settle the matter by agreement between the parties; that all questions of general conduct and of false certification should be reported upon in the first instance by the Local Medical Committee; that the practitioner should have a right of appeal to the Courts, not only on the ground of improper procedure, but because the penalty is out of proportion to the offence; and—a most important point, in our view—that no practitioner ought to be

removed from the panel without the right of appeal to a central professional committee, nor removed except on the advice of such committee.

The last two sections deal with administration and remuneration. Here the Association urges that the administration of cash benefits should be separated from medical benefit, and the latter linked up with all other local health services under an *ad hoc* local authority or a statutory committee representative of all interests, with a chief administrative medical officer and a statutory local medical committee. It declares that the remuneration of the profession should be settled centrally on its merits by negotiation between the Ministry of Health and a central negotiating body; that the general practitioner service should be remunerated by capitation fee, and the consultant and specialist service according to a tariff; that the profession should be completely assured that the calculation of the Central Practitioners' Fund and its division between areas is as nearly as possible exact; that, as a matter of principle, insurance remuneration ought to compare not unfavourably with what is earned in private practice of a corresponding kind; and that the present capitation fee of 9s. is still too low, while the additional grant to rural practitioners needs reconsideration.

We propose now briefly to indicate for purposes of comparison the changes of substance that have been made.

Part I is entirely new, and is intended to make clear to the Royal Commission the fact that the Association is in a position to voice the opinions of the medical profession of the country in this matter. Details are given of the steps taken by the Association in order to secure that every registered practitioner in Great Britain has been afforded an opportunity of forming an opinion upon the Evidence and of making known his views thereon to his fellow practitioners.

Paragraphs 1 to 9 of Part II remain unchanged. In paragraphs 10 and 11 minor corrections only have been made. Paragraph 12 consists of the first part of the earlier paragraph bearing that number amplified to make clear the Association's view that provision for medical advice and treatment for certain of those persons comprised in the second and third groups, referred to in paragraph 11 (workers not under a contract of service but in an economic position like that of present insured persons and those economically dependent upon such persons), should be by way of a family doctor with free choice, rather than by State-paid or rate-paid medical officers or by the establishment of treatment clinics; and that similarly the same conditions should be observed in any provision made for the fourth group—namely, the destitute. Paragraph 13 brings together the second part of old paragraph 13 and the first sentence of old paragraph 14, amended by drawing attention to the body of opinion in the profession which doubts the possibility of including dependants of the poorly paid earners, and the equally large body of opinion as to the urgent need for medical attendance upon the same class of dependants. Here it should be observed that the Memorandum of Evidence is emphatically against any suggestion of admitting all dependants, and indicates the considerable difficulties that might arise in the way of admitting dependants of the poorer insured, though it is in favour of doing this if it can be managed, subject to certain conditions. Around this matter there has been wide divergence of opinion, and it is important to note the terms in which the controversial point is settled. The next four paragraphs have been recast in form.

but not in substance, with the object of putting certain points more clearly and forcibly. To paragraph 18 has been added a sentence making quite plain that the interests of existing medical officers shall not be allowed to suffer as a result of any change. Paragraphs 19 to 27 remain as they were. Paragraph 28 has been amended so as to make clear that any change does not mean the immediate abolition of appointments of whole-time tuberculosis and venereal disease medical officers.

Paragraph 29, which deals with maternity work, has also been amended in three directions. The second sentence now includes words which place it beyond doubt that the maternity scheme referred to shall only apply to insured women and the wives of insured men. Further conditions have been added which the Association holds must be observed if any maternity scheme is included under the Insurance Acts—namely, (a) that any insurance practitioner must be free to undertake or decline this work without in any way affecting his interests otherwise, and (b) that any complaint as to treatment must be referred to a solely professional committee on which the local administrative authority should be represented by its medical officers. Thirdly, it is stated plainly that any registered practitioner must be at liberty to place his or her name upon the list for maternity purposes. In order to clear up some misunderstandings arising out of this paragraph, it may be well to point out that medical supervision of any woman during pregnancy means that the medical practitioner undertaking the work would be responsible for the general supervision of the health of the patient during pregnancy. Except for a few verbal amendments, the remaining paragraphs of the document and its appendices are as in the original draft Memorandum.

#### MEDICAL ASPECTS OF HOLIDAYS.

SIR HUMPHRY ROLLESTON, Bart., President of the Royal College of Physicians of London, read, on February 20th, an interesting paper before the Liverpool Medical Institution on some medical aspects of holidays. He touched historically on the evolution of the modern holiday from the holy days and saints' days of bygone generations. Holidays, he said, were essential to the well-being of mankind, and as in the individual's life the law of fluctuation between complete activity and complete rest was physiologically necessary, so similarly, in the stress and strain of life, a diastolic period was needed wherein the organism might be recreated physically and mentally. It had, indeed, been said that overwork was no more meritorious than overeating or other form of excess. He mentioned the lives of Sir James Paget and Sir Henry Holland. The former did without a holiday for fifteen years during his hard struggle as a young surgeon-pathologist. The latter for nearly sixty years spent every year two months in travel. In both men the span of life was the same. As years increased the zest for holidays became less keen. Inertia and a clinging to home comforts took the place of the keenness of youth for change and new experiences. Some medical men seemed to keep well on no holidays at all, and relied on walking exercise to keep them fit for their work. On the other hand, many holidays had been beneficial in warding off the collapse of a medical man who had been too preoccupied to take one until a warning had aroused him to the importance of recreation. Sir Humphry proceeded to consider two different aspects of holidays—first, that of recreation, and secondly, that of rest and repair. The holiday should be in essence a complete change from the daily routine, and naturally would depend largely on

temperament and taste. A well arranged week-end habit, involving bodily and mental ease, might obviate a prolonged holiday of six to eight weeks. On the other hand, a Continental holiday well planned had the great advantage of removing effectively from the intended recipient calls, consultations, and certificates. Such holidays were educative and pleasurable, and when taken in a leisurely way were of inestimable benefit. Medical congresses were in this respect of value, and corrective in preventing an all too common tendency to insularity in our ideas and thoughts. Holidays might fail if judicious preparation were wanting, especially in those who missed too much the comforts and amenities of their home life, by suddenly embarking on strenuous physical exertion. He mentioned "diseases due to holidays," and divided them into two—(1) those while actually away from home, and (2) those arising after return but due to infection acquired while on holiday or on the return journey (for example, in sleeping cars). Apparently acquired immunity to microbial infection runs the risk of being lost after a long holiday, and Sir James Paget was of that opinion. In advising patients about the health resort where holidays should be taken, Sir Humphry thought that much more careful consideration should be given to each case, and mental and physical factors should be taken into account. He cited the late Sir Hermann Weber, who paid particular attention to hydrology, climatology, and balneology in the important matter of holidays for his patients. Several members spoke and gave their own experience of holidays, supporting the views expressed by the lecturer. The President, Mr. R. C. Dun, expressed on behalf of the members the pleasure they had in listening to the paper and the value of the suggestions it contained.

#### ON VARIATION OF BACTERIA.

DR. BERGSTRAND of Stockholm has published, in English, in *Acta Pathologica et Microbiologica Scandinavica*, vol. i, Fasc. 2, 1924, an interesting and important article on variations of bacteria. He shows from his observations that an original culture of *Bacillus coli* contained a motile and a non-motile variety; the latter soon formed varieties, but the former only after a fairly long interval. Photomicrographs are given of varieties appearing in the form of secondary colonies on agar plates, implanted from pure cultures of the motile as well as of the non-motile type; the latter were the more numerous. Not only did the form and colour of the varieties and the morphology of the separate micro-organisms vary, but also the biological characters—for example, the power of producing mucus and fermenting sugars. Serological characters have been considered most stable and specific, and Bergstrand gives a summary of the important investigations of Weil on the agglutination of a *proteus* strain X by serum of typhoid. "If we did not know," says Weil, "that the strains (of *proteus*) originated from one single cell we could not believe them to be identical, at most we might suppose that they were related, so serologically different are they." Weil's co-workers showed also that bacteria belonging to the typhoid, paratyphoid-enteritidis, and dysentery groups behave in a similar manner. The discovery of the Twort-d'Herelle phenomenon showed that all bacteria exposed to a lytic agent actively give rise to varieties. Bergstrand refers to the investigations of Hansen on the varieties occurring from an absolutely pure culture of yeast, and concludes "that everything now goes to show that bacteria and yeast behave in an identical manner." The modifications occurring in bacteria are of great importance, for they may afford a solution of many problems concerning the spread and changing character of epidemics. We see that in these beginnings of life mutation and evolution are constantly occurring.

#### THE OPIUM CONFERENCES AT GENEVA.

THE conferences called by the League of Nations to consider certain aspects of the traffic in opium and dangerous drugs in the light of the International Convention signed at the Hague in 1912 have at last terminated their labours. The two conferences or their committees have been more or less continuously in session since November last. The first and smaller conference, representative of those countries only which produce opium, at first prepared a draft agreement which was not signed by any of the delegations except that of India. It finally prepared a convention and protocol which were signed on February 11th by all the delegates except the Chinese. It provides for Governmental control of opium, the cessation of opium farming, the prohibition of sale to minors, a reduction of the number of retail shops for sale of the drug, and measures for stopping illicit traffic. The suppression of the export trade in opium for smoking, which the Hague Convention of 1912 sought to prohibit at once or as soon as possible, is to take effect within fifteen years after the League of Nations is satisfied that smuggling shall have been effectively stopped. The Japanese delegate, Mr. Sugimura, criticized the suspensory character of the proposal, and expressed the opinion that the withdrawal of China rendered its operation very difficult. The second and larger conference, which comprised delegates from forty-one States at its commencement, held its final session on February 19th, when a convention and protocol representing the outcome of its labours were signed. These dealt with the means for regulating the trade in dangerous drugs. Unfortunately the delegations of the United States and China withdrew from the later sessions of the second conference, and for the present, at any rate, they are not parties to the agreements arrived at. M. Zahle, the chairman of the second conference, in reviewing its work, said it had been "the most difficult in the history of the League," and that it "could not boast of having reached complete success." The new convention is intended to implement the Hague Convention of 1912, and to furnish machinery for giving effect to its provisions. A permanent Central Control Board is to be set up consisting of eight persons appointed by the Council of the League, the United States, and Germany. This board is to collect information as to the amount of drugs required for medical and scientific purposes in each country for internal consumption, and also as to the raw materials imported, the amount of drugs manufactured, and the stocks in hand. If excess of stock is proved export to such country will be suspended. Import and export of the drugs are to be effected only under Government certificates, and steps are to be taken to put down contraband trade. The convention is not to come into force until it has been ratified by ten Powers, including seven of the States who nominate the central board, and two must be permanent members of the Council of the League.

#### BOARDING-SCHOOL FOOD.

THE Home Office has issued a most instructive pamphlet entitled *Some Problems of Feeding in Home Office Schools*.<sup>1</sup> It should make a wide appeal to those who have the care of children in resident schools, whether private or under some authority. The problem is the same in all. It is now evident that a diet table based upon caloric values alone is not sufficient. Our conception is widened to include significant though less defined constituents of food. The importance of a practical application of the known facts of dietary in regard to children cannot be too strongly emphasized. Proper feeding plays an essential part in the production of a fit and efficient race. In a school where the children reside for long periods, practi-

<sup>1</sup> H.M. Stationery Office, 1924, pp. 12. Price 3d.

cally without holidays, as in the Home Office schools, the feeding arrangements must be arranged with particular care. The pamphlet is written by Dr. G. H. Culverwell, medical inspector of the Children's Branch, Home Office, and is based upon a paper read by him at the triennial Conference of Managers and Superintendents of Preventive and Reformatory Institutions in Glasgow last June. He deals with the "growth impulse" and the power that can be exercised over it; the need for the recognition of individual variations; the need for variety, and especially the avoidance of anything that will bring about a rotation of meals the sequence of which will be known to the children: "We should never be satisfied with an arrangement by which the same meals recur monotonously on the same day of each week, nor with one in which the particular first course is always followed by the same pudding. A rota of dinners covering at least two weeks is very desirable, and even then it is well to provide for the insertion at intervals of a surprise meal of some food which cannot ordinarily be supplied." Stress is laid upon skilful cooking. The balance of food as determined by vitamin selection is very clearly set out, and will be understood by the lay reader; it is put in such fashion that its importance cannot be missed. Finally, there is a summary, which might well be printed in large type, framed, and hung in the office of every school steward; it is as follows: "Care is necessary to meet the food needs of the individual child. Try to secure the free supply of bread and fat. Try to include in your dietary a full supply of readily assimilable protein food. Include all the milk you can afford. Regard a failure in the fresh vegetable supply much as you would a failure in the school water supply. If you cannot get fresh vegetables, give oranges and increase the dripping. Bear in mind that dried pulses cannot take the place of fresh vegetables. Avoid overcooking. Never forget that bread, margarine, lard, rice, and tinned meat will not help with your vitamin supply. If any number of the children in your school are not making the physical progress that they should, make certain the fault is not with the dietary."

#### INFLUENZA.

THE deaths from influenza in the great towns in England increased last week from 291 to 354, in London from 76 to 92. Six cities other than London recorded 10 or more deaths—namely, Birmingham (10), Liverpool (10), Manchester (18), Salford (10), Rochdale (11), Leeds (12). Notifications of primary pneumonia were less numerous—namely, 1,742 (1,778 in the previous week); and the epidemic appears to be waning in the North, although in the South it is still perhaps not at its height. Last week's increase of deaths was not, however, so large as might have been anticipated, and in general the disease continues to be mild. It is satisfactory to find from the bulletins, the issue of which has now been suspended, that the King is making a slow if sure recovery, although at the time of writing convalescence has not been established. The attack of influenza from which His Majesty suffered was at the onset somewhat severe, and the bronchitis by which it was complicated extended to the bases of the lungs—a form of the malady which is apt to be tedious and resistant. The King's medical advisers have recommended, in order to secure complete restoration of health and fitness, that when the stage of convalescence has been reached His Majesty should proceed to the South of Europe and cruise in his yacht for a few weeks. His Majesty will probably accept this advice without reluctance, for since his days in the Royal Navy he has retained his love of the sea, as is shown by his keenness as a racing yachtsman. It is announced that the royal steam yacht *Victoria and Albert*, which is at Portsmouth, will be ready to sail at short notice to meet His Majesty at a Riviera port.

#### THE CARE OF CRIPPLES.

WE owe to Mr. W. A. Cochrane, assistant surgeon to the Edinburgh Royal Infirmary, an apology for an unfortunate confusion which arose in the notice of the *Cripples' Journal* for January published on February 21st (p. 376). That issue contained an article on crippled children in Scotland by the Rev. T. Ratcliffe Barnett, to which Mr. Cochrane added an appendix. It was Mr. Ratcliffe Barnett, and not Mr. Cochrane, who confessed that it was during the war he learnt the first meaning of the word "orthopaedic." The attribution of so unlikely an opinion to Mr. Cochrane ought to have been observed before the paragraph was printed; even Homer sometimes nodded, and an ordinary everyday editor may hope to be forgiven an occasional lapse. The point Mr. Cochrane sought to enforce was that, though the experience of past years has gone far to determine the value of particular methods for securing the welfare of crippled children, yet, if the cripple is ever to become an economic asset, organization will be necessary to make certain of continuity of supervision and after-treatment all through the growing period of the child. In severe cases, he said, there must be institutional care, so that quite apart from removing the physical handicap the educational and vocational training of the crippled child may go on. The people themselves, he went on to say, must be educated about the crippling disabilities of the children in their homes. Not only must the parents be induced to take advantage of the resources even now available, but the public must be stimulated to realize its responsibilities. He referred to the colossal scheme for the care of crippled children in America, which has resulted in the system of Shriners' Hospitals within the last two years. After preliminary negotiations among a few individuals there sprung up a national scheme for the treatment of cripples which now embraces the whole of America, and has a hospital as far west as Honolulu. He made reference also to what is now being done in England through what is commonly called the Shropshire organization, which is rapidly spreading to other parts of the country. Mr. Cochrane appealed to Scotland to do at least as well, and we do not doubt that his appeal will meet with a generous response.

#### SCIENTIFIC HISTORY.

SCIENTIFIC inventions have a certain fascination for the minds of most people. It is never difficult to get an audience to listen, at any rate for a few minutes, to a description of a new machine for digging coal, a new type of sailing ship, a new disease, or a new helicopter. Newspaper proprietors are well acquainted with this public thirst for elementary scientific knowledge, and they cater for it generously, serving up the discovery in an attractive little article, accompanied by a picture on the back page. But popular curiosity about scientific things is quickly set at rest, and most people are content with a sentence or two of explanation. Ordinary people continue to use the telephone, to "listen in" with wireless, to enjoy electric light, and to travel about rapidly, with little if any accurate knowledge of the discoveries and scientific principles on which these conveniences depend. This ignorance may not persist in the future, because children will learn about scientific discoveries at school. It is interesting to speculate on the way in which scientific discoveries may alter the plan of teaching the school curriculum. Of course, physics will have to be taught in a different way, and be made more interesting by its practical application to familiar things. The method of teaching history is likely to be changed also. Chapters in history books are no longer divided by the deaths of kings, or even by battles and peace treaties. In the history books of the future a chapter may begin with the discovery of the steam engine, another may date from

the first successful aeroplane flight, another from the discovery of microbes, another, perhaps, from the synthetic manufacture of gold. This train of thought has been suggested to us by a recent book by Dr. Franklin Harris of Brigham Young University, entitled *Scientific Research and Human Welfare*.<sup>1</sup> It is a history book of scientific discovery. Beginning with health, the author describes the discovery of causes of disease, the development of painless surgery, the story of x rays, and the successful search for specific remedies. In a section on communication he gives the history of the telegraph, the telephone, and wireless. Succeeding sections deal with discoveries in transportation, illumination, agriculture, engineering, mining, and manufacture. This ambitious programme is covered in about 370 pages, and the book ends with a chronology of scientific discoveries extending from 600 B.C., when the Greeks first learnt how to extract iron and the precious metals, to A.D. 1922, when the African sleeping sickness remedy, Bayer 205, was discovered. It must have been a great labour to collect together all the information, for the book is a veritable encyclopaedia, and ordinary readers will be bewildered by the enormous number of facts they can never hope to remember. But it would do a great deal of good if it made the general public realize how much comfort and convenience they owe to scientific research.

#### ANTIQUE MICROSCOPES.

SALES by auction have a fascination for certain people, apart from the value or beauty of the articles offered for sale. No doubt those habitual frequenters of Christie's who never bid find pleasure or excitement in watching a keen contest between rival buyers, and their pleasure is akin to that experienced by the spectators of a race or any other competition. Of all London auction rooms Stevens's may be reckoned one of the most attractive. Although it specializes in scientific instruments, its activities are by no means confined to them. At the sale on February 17th the antique microscopes were cheek by jowl with the bulbs and evergreen shrubs which lingered from the sale of the previous day, and we have known a parcel of hams to figure in the same catalogue as photographic lenses and other optical instruments and the most intimate personal effects. The genial presence of the veteran auctioneer who has occupied the rostrum for more than sixty years adds the finishing touch to the scene, and embodies the genius *loci*. Here the antique microscopes to which reference was made in our issue of February 14th were sold last week. Some high prices were paid, one lot—a large ornate silver instrument—fetching £360. An original modification of the Hooke microscope dating from the last quarter of the seventeenth century fetched £160. The auctioneer asserted this to be oldest microscope known, but it does not seem at all certain that it was made by or for Hooke himself. Other lots fetched good prices. One of the smallest but most perfect instruments in the sale—a tiny compound microscope by an Italian maker—went for £45. It is to be hoped that some of the best lots have been secured for our museums, for at present the national collections are not rich in this respect. In the Science Museum at South Kensington there is, it is true, a collection which, though small, is representative, but the majority, if not all, of the exhibits are only lent, and might be removed at any time. Although doubtless most of these instruments were used more for amusement than for scientific research, they are none the less of interest as the types from which scientific modern microscopes were developed. The dissecting microscopes of Lieberkühn's pattern, which really were used for

anatomical and physiological purposes, seem, however, to have left no modern descendants. These—one of them dating from the middle of the eighteenth century fetched £12—look at first sight like anything rather than microscopes. It has been stated in the press that Sir Frank Crisp had frequently expressed his intention to present his collection to the Science Museum at South Kensington. We judge from the comments made on this statement by Dr. R. T. Gunther in a letter to *Nature* that Sir Frank Crisp did not make up his mind as to the disposal of his collection, although it is quite clear that he wished it to be made of use in the preparation of a comprehensive history of the microscope. Its dispersal is all the more grievous a calamity because, as Dr. Gunther tells us, "many parts of the instruments have got mixed, that historic examples have been divorced from their history," and "that the collection has been distributed without having been properly catalogued." In this connexion it should be noted that a loose-leaved illustrated catalogue, which was stated to contain voluminous notes and descriptions of only the more modern part of the collection, formed Lot 175 in the sale and fetched £9.

#### IODINE FOR INTERNAL USE.

A COMMUNICATION we have received from Dr. P. C. Brett directs attention to a change in the composition of the tincture of iodine of the French *Codex*. It is now officially prepared from iodine with potassium iodide, whereas formerly it consisted only of iodine dissolved in alcohol. Dr. Brett suggests that it is being prescribed with increasing frequency in this country, and expresses a doubt whether it is known that the name does not designate what it must be presumed the prescriber desires, for the new tincture of the *Codex* is not unlike that of the *British Pharmacopoeia*. Iodine is so briskly reactive that it enters into chemical reaction with the first portion of food or tissue met. We have seen a mixture in which the iodine had been reduced in a few days to half the amount originally present, the rest having been consumed by the cork. Some of the compounds formed with food would be stable; others would slowly set the iodine free again. Thus the character of the therapeutic effect might vary according to the quantity of food in the stomach. When prescribed with potassium iodide, iodine wanders a little less readily into other combinations; its combination with potassium iodide, although weak, depends on chemical affinity. We do not know whether the old formula of the French *Codex* was expressly designed to produce a tincture devoid of potassium iodide, or whether it was considered that the amount of potassium iodide in the new tincture was so small as to have no appreciable physiological effect. It occurs to us that there are other ways open to exploration for the exhibition of iodine by which the rapidity of its chemical action might be moderated. If the iodine were dissolved in an inert oil such as liquid paraffin, and the oil dispensed as an emulsion, the chemical reactivity of the iodine would be damped, and there would be less interference with the simplest form of its physiological action.

Among the fifteen candidates recommended by the President and Council of the Royal Society last week for election to be Fellows are: Dr. C. A. Lovatt Evans, professor of physiology at St. Bartholomew's Hospital Medical School (University of London); Dr. F. Wood Jones, professor of anatomy in the University of Adelaide; Dr. Edward Mellanby, professor of pharmacology in the University of Sheffield and physician to the Royal Infirmary there; and Dr. James A. Murray, director of the Imperial Cancer Research Fund.

## EPSOM COLLEGE CHAPEL.

CONSECRATION BY THE BISHOP OF WINCHESTER.

The nave of Epsom College Chapel, which has been rebuilt on an enlarged scale as a memorial to the 140 Old Epsomians who fell in the war, was consecrated by the Bishop of Winchester on February 21st. The addition completes the original design of thirty years ago, when the late Sir Arthur Blomfield designed the chancel, which was built by Messrs. Dorey and Sons. Mr. Arthur Blomfield, the architect of the new nave, has continued his father's designs, and Mr. John Dorey has similarly completed the work begun by his father. Sir Henry Morris, Bt., who was present as a boy at the opening of the school in 1855, was a member of the council for thirty-six years and recently resigned the office of treasurer, which he held for eighteen years, was one of the most energetic supporters of the project, and it was largely due to his advocacy that this work was started at a time when the available funds seemed hardly adequate. The cost of the rebuilding has been £11,500, of which about £2,000 remains to be raised. The money has been subscribed mainly by the relatives of the fallen, by Old Epsomians, and by parents of boys now in the school. To provide for the increased number of boys the nave has been enlarged in width and length even beyond the original designs, and, with the addition of the western gallery, furnishes accommodation now for 650. The nave is built of red brick inside and outside, with Bath stone windows and dressings; the roof is covered with green slates; and the spire of the bell turret over the new organ chamber, on the south side of the nave, has been finished with split oak shingles. A new oak front has been fitted to the organ chamber to match the other woodwork in the chapel, which is of Austrian oak. The floor of the nave is laid with oak blocks, and the seating is by chairs.

EPSOM COLLEGE CHAPEL.

Fourteen hexagonal coronas of wood, decorated in colour, carry the electric lighting for the nave, the chancel being also illuminated by strips on the walls. A new hot-water system has been introduced. A tablet has been inserted on the north wall with a list of 140 names, omitting honours and awards. During the ceremony three wreaths were placed beneath it by the head prefect, the second master, and the president of the Old Epsomian Club.

The Bishop of Winchester in his address took for his text Revelation xxii, 2: "The leaves of the tree were for the healing of the nations." He referred to the legend which

connected the Tree of Life in the Garden of Eden with the Cross of Calvary. When Adam was dying, Seth, his eldest son, was said to have endeavoured to bring a branch of the tree to save his father's life, but arrived too late. Solomon subsequently endeavoured to incorporate the tree in the Temple building, but nowhere would it fit. It was then cast aside to be used as a bridge; and, when afterwards it was thrown into a well, it conferred healing properties on the water. Eventually, the legend concludes, the tree was used for the Cross. So in later times the sign of the Cross had

stood for the healing of the nations. Those who had died for the healing of a sick world from its commercialism, crass nationalism, and individual selfishness, had in very truth made the sign of the Cross, and henceforth the school that sent them forth was holy ground. The day was, therefore, one of solemn dedication for the school, and the consecration of the chapel would find its completion in the future lives of those who would worship within its walls. The present generation had received a challenge to effect the completion of the healing of the world. This was most particularly true of the medical profession, into which so many boys of Epsom College were intending to enter. The very foundation of healing, whether of nations or of individuals, was service and sacrifice.

## England and Wales.

DR. WARDROP GRIFFITH OF LEEDS.

DR. T. WARDROP GRIFFITH has tendered to the council of the University of Leeds his resignation of the professorship of medicine. In his letter to the council he pointed out that in harmony with the rules of the General Infirmary at Leeds he becomes a member of the consulting staff next September, by which time he will have served for twenty years on the full staff. It was this fact, he said, which had led him to anticipate the age limit for the tenure of office which attaches to professorships in the University; for although in Leeds members of the consulting staff have, happily, the privilege of admitting a limited number of patients to be under their care in the infirmary and continue to work within its walls, he felt that the best interests of the University would be served if he did not retain the professorship after he had retired from the full staff and the regular routine teaching which that involved.

At its meeting on February 18th the council of the University adopted the following resolution:

The council accepts the resignation of the senior professor—Professor T. Wardrop Griffith—with deep regret. He was appointed to the chair of anatomy in 1887 and transferred to the chair of medicine in 1910, a continuous record of thirty-eight years. He began work in the old medical school in Park Street, and took an active share in the construction of the new school in Thoresby Place, in which he established one of the best anatomical departments in the kingdom, filling it with many valuable collections, and in his own hand. His assiduous attention rendered his tenure of office of the chair of anatomy little different from a full-time office, as every hour spared from hospital work and consulting

practice was spent with energy in the department, and there is no department of its kind more entirely the creation of one man's zeal and love. In his tenure of the chair of medicine he has added to the lustre of its history by the high quality of his observations in clinical fields and able exposition of his subject, attaining an eminence acknowledged by his admission to the Order of St. Michael and St. George and the conferment of the honorary Doctorate of Laws by his own University of Aberdeen. In both departments his courses of lectures have been noted for their vivid quality and the perfection of arrangement and delivery. In the Faculty and University he has played an important part by sound advice and an example of devotion, for which a heavy debt of gratitude and affection is due. His resignation marks the completion of one of the soundest pillars on which the school has been reared, and the council, looking forward to the support which will remain in his work and the effects of his work, desires to record its appreciation of his most valuable and enthusiastic services, its grateful thanks for the distinction he has brought to the University, and its cordial hope that he will, for many years to come, enjoy the ability to pursue the practice of his profession and add to the many contributions by which he has advanced the cause of medicine.

The rule of Leeds Infirmary, which permits a consulting member of the staff to retain a certain number of beds (we believe six) is a wise one, and we could have wished that Dr. Griffith had considered that it justified him in retaining his chair, though perhaps the pressure of private work, in the prosecution of which neither the profession nor the public in the West Riding is likely to allow him to relax, has had something to do with his decision; there will be nothing to prevent him from giving us in the future further examples of his great capacity as a clinical lecturer.

ARTIFICIAL SUNLIGHT TREATMENT AND THE PUBLIC  
TUBERCULOSIS SERVICE.

THE London County Council has had before it a request from the Bermondsey Borough Council for a grant towards the cost of a scheme for the provision and equipment of

premises suitable for giving artificial or natural sunlight treatment to tuberculous or other persons, the scheme to be regarded as a development of or adjunct to the existing tuberculo-is dispensary service in the borough. The Public Health Committee of the County Council has reported that while, in expert hands, the success of artificial light treatment in lupus is incontestable, it is still to some extent in an experimental stage in surgical tuberculosis, and appears to be not at all suitable in all types of cases of pulmonary tuberculosis. The committee has also pointed out that treatment by artificial light is available at various general and special hospitals in London, and is not limited to tuberculous cases. The London Hospital, Guy's, and St. Thomas's are increasing their facilities therefor. It appears unquestionable, according to the committee, that there is sufficient provision in the hospitals to enable a large-scale test of the treatment to be made, and it is taking steps with a view to arrangements for such a test being proceeded with as speedily as possible. It is felt, therefore, that provision by borough councils of facilities for treatment by artificial light as part of the arrangements at tuberculosis dispensaries should not at present be approved by the County Council for the purposes of grant.

#### MEDICAL HYDROLOGY IN GREAT BRITAIN.

The Committee for the Study of Medical Hydrology in Great Britain has arranged for a third course to be held at the University of London, from April 27th to May 2nd. The subjects to be dealt with include: types of water which occur in nature; hydro-geology; the capillary circulation of the skin; and the use of medicinal waters, baths, and heat in the treatment of disease. Demonstrations on the analysis of waters and of the effects of open air and sunshine on the body will be given. In connexion with this course visits will be paid to Buxton and Matlock. Full particulars may be obtained from Miss Hilda Fox, c/o University Extension Department of the University of London, South Kensington, S.W.7.

## Scotland.

#### EDINBURGH UNIVERSITY CAMERON PRIZE.

At a meeting of the University Court of Edinburgh University on February 16th it was announced that the Senatus had resolved, on the recommendation of the Faculty of Medicine, to award the Cameron Prize for 1925 to Professor R. Magnus of Utrecht University, Holland. This prize, of the value of about £200, is awarded annually to a person who, in the course of the five years immediately preceding, has made some highly important and valuable addition to practical therapeutics.

#### ROYAL SOCIETY OF EDINBURGH.

The following are among the thirty-eight candidates recommended for election as Fellows of the Royal Society of Edinburgh on March 9th: Dr. T. W. Naylor Barlow, O.B.E., past-president of the Incorporated Society of Medical Officers of Health; Dr. Sahay Ram Bose, professor of botany in the Carmichael Medical College, Calcutta; Dr. Henry Dreyer, lecturer in physiology, University of Edinburgh; Dr. Dr. Middleton Greig, conservator of the museum of the Royal College of Surgeons, Edinburgh; Dr. W. Henry Lang, F.R.S., Barker professor of cryptogamic botany, University of Manchester; Dr. Richard L. Sutton, professor of diseases of the skin, University of Kansas School of Medicine, U.S.A.; Wing Commander Harry M. S. Turner, M.B.E., Royal Air Force Medical Service; and Mr. David P. D. Wilkie, O.B.E., professor of surgery, University of Edinburgh.

#### EDINBURGH EDUCATION AUTHORITY AND MENTAL DEFECT.

A joint conference of representatives of the Edinburgh and Lothians Education Authorities was held on February 11th to consider the question of accommodation for mentally defective children. Dr. Sym (Edinburgh) occupied the chair, and in opening the discussion referred to the position

in Edinburgh, where he said that in special schools and in special classes in ordinary schools about 420 defective children who were educable were under training, and in other institutions there were uneducable children to the number of 25 or 27. The problem of mental defect had two very difficult aspects. One was what type of education should be given, and the other was what would become of the children after the age of 16. It was useless to send children to special schools and then turn them adrift. Means must be devised for dealing with mentally defective adolescents and adults. The Rev. Charles Dunn (Uphall) said that in Linlithgowshire there were 186 mentally defective children, of whom 26 were not educable. The authority had special classes, but was not satisfied that these classes fully met what was wanted. It had before it a proposal to establish a farm colony for educable mental defectives, who might be made self-supporting so long as they were under supervision; a farm colony which had been established near Manchester had been found very satisfactory. Dr. Inch recalled that five years ago the Midlothian authority convened a meeting of representatives in the seven south-eastern counties of Scotland, but no conclusion was reached owing to failure of support from the Education Department, Board of Health, and Board of Control. In Midlothian the education authority had started a special school, and meant to start another. Mr. Kemp (executive officer, Midlothian) said that he was a strong believer in not removing the children from their homes if possible, for when children were taken away parents lost interest in them, and they were afterwards looked upon as a nuisance. It was wonderful what could be achieved by a sympathetic teacher in the special classes of day schools. Mr. William Taylor (Edinburgh) said the proper place to deal with educables was in special classes, and it was unwise to remove children to an institution, which had the effect of branding them as mental defectives. He estimated that 80 per cent. of the children who attended the special classes in Edinburgh found occupation on leaving school. It was agreed that the representatives should report to their various authorities, and that another conference should be held after they had received instructions, particularly in regard to a proposal for co-operation with parish councils.

#### REDLANDS HOSPITAL FOR WOMEN, GLASGOW.

Redlands Hospital for Women, formerly known as the Glasgow Women's Private Hospital, is situated in the west end of Glasgow, and was formerly a large mansion. It has been altered and enlarged, and is now a well equipped hospital of fifty beds. It is the only hospital of its kind in the West of Scotland, and with the exception of four honorary consulting officers is staffed by medical women. The patients all contribute to their maintenance. Those in the wards pay 30s. weekly, but receive free medical and surgical attendance. There are rooms with four beds, two beds, and one bed; the payments for these range from £2 2s. to £4 4s. a week, and the patients occupying them may be charged a modified fee by the doctor in attendance. There is also a well equipped maternity department, having a ward and single-room accommodation and an up-to-date labour room. At the formal opening of the hospital by Viscountess Rhondda, Mrs. Greenlees occupied the chair, and among those present were Miss Melville (convener of the executive committee), Mrs. D. M. Ross, Dr. Alice McLaren (senior member of the staff), Miss McLean (matron), and Mrs. Craig (honorary secretary). Mrs. Greenlees said that the hospital had started in 1903 with eight beds. It had removed to larger premises (sixteen beds) in 1915; but that accommodation soon proved too limited, and finally, in August last, the hospital was moved to Redlands, which provided ample accommodation for fifty patients. Lady Rhondda, in declaring the hospital open, said that in all the big towns the need for such hospitals was felt and supplied. The demand was often inarticulate, but nevertheless urgent. Undoubtedly many women went on suffering too long where there was no facility to consult one of their own sex. She sincerely hoped that the £20,000 required by the new hospital would soon be oversubscribed. After votes of thanks had been adopted to Lady Rhondda and Mrs. Greenlees, those present had an opportunity of inspecting the hospital.

## GLASGOW CONVALESCENT HOME.

The report presented to the sixtieth annual general meeting of the Glasgow Convalescent Home stated that during the past year 1,428 patients had been admitted, of whom 422 were convalescents from the Royal and Western Infirmarys, while 985 had been admitted on subscribers' recommendations from other sources. The average stay of patients had been 13.4 days, and the cost had been 11s. 4d. a patient per week as compared with 12s. 3d. in the previous year. The ordinary income for the year had been £3,887, which was £304 less than the ordinary expenditure. The Lord Dean of Guild (Dr. R. T. Moore), moving the adoption of the report, stated that the home was established sixty years ago, and observed that it was of special interest to find from the records that the late Lord Lister had been intimately connected with the founding of the institution; for a number of years from 1865 onwards he had been one of the board of managers, and had assisted from the very commencement of the home in raising funds and in drafting rules. Mr. Kerr, who moved a vote of thanks to the directors and staff of the home, mentioned a further point in connexion with Lord Lister, in that he had carried out some of his experiments in a druggist's shop at the corner of Glassford Street and Wilson Street, an establishment which had celebrated its hundredth year in 1924; the exterior of the premises had remained unchanged during the whole of that period.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The House of Commons has been chiefly occupied with Supplementary Estimates and the Air Estimates this week. The Supplementary Estimates for Expenses under the National Health Insurance Acts were reported without discussion, and there was only a brief debate on the Supplementary Estimate for the Ministry of Pensions, the point at issue being final awards. On this point Major Cohen and other members have put down a motion asking for a Select Committee of Inquiry.

## Indian Medical Service.

Lord Sydenham has given notice that at an early date he will, in the House of Lords, ask the Secretary of State for India the present position of the British element in the Indian Medical Service as regards strength on the establishment and recruiting in this country; and also whether measures are in contemplation adequately to fulfil the medical requirements of the Indian Army, British residents (official and non-official), and the civil hospitals, and to secure the progress of medical science in all its branches throughout India.

## Public Health Commissioner, India.

Mr. William Graham, on February 23rd, asked Earl Winterton, the Under Secretary of State for India, whether he was aware in the post of Public Health Commissioner with the Government of India an officer who did not hold a diploma in public health, notwithstanding the fact that it was specifically laid down that no officer was to be accepted for any post in the public health department of India unless he possessed such a diploma; and whether he was aware that when in 1918 a similar case arose the officer holding Earl Winterton replied that the answer to both questions was in the affirmative.

Mr. Graham further asked why the appointment was confirmed in the case of the present officer, "thus blocking promotion to men in the service who held the obligatory qualification for the post." Earl Winterton, in response, promised that he would furnish a detailed statement of the high qualifications and wide experience in the opinion of the Government of India fitted the officer in question for the post of public health commissioner.

This statement, which was circulated to members, showed that the officer to whom Mr. Graham referred was Lieut.-Colonel Graham, who graduated M.B., C.M. Glas., with high commendation, and spent four and a half years in post-graduate work and hospital resident posts before passing into the Indian Medical Service in January, 1900. He was, the statement added, first in the London examination and again headed the list in passing out of Netley University, and obtained the certificate of the Liverpool Tropical School, taking the first place, on both occasions. In April, 1908, from then, with the exception of one and a half years during which he acted as a civil surgeon, he was engaged on research, epidemiological, and public health work until mobilized for the

great war in 1911. During this period he served on sanitary and public health committees in the United Provinces. During the war Colonel Graham was employed exclusively on sanitary and public health work. After service in Egypt he was transferred uneventfully to Iraq, where, in December, 1916, he was appointed Chief Sanitary Adviser to the Forces, which position he retained for three and half years. He was responsible for the commencement of all civil health control throughout the occupied area in Iraq, where he became Inspector-General of Health Services. On his return to India in 1921 Colonel Graham was appointed officiating Public Health Commissioner with the Government of India, which post he still holds.

**Welsh Regional Pensions Office.**—The Parliamentary Secretary to the Ministry of Pensions, Colonel Stanley, on February 23rd, informed Mr. Morris that he could not reconsider the decision to close the Welsh regional pensions office at Cardiff. The Welsh members during debates in the previous week had made a protest which was supported by Mr. Lloyd George, against the decision. It was stated that the saving in administration would be £500 a year.

**Nursing Bill.**—The introduction of the Nursing Homes (Registries) Bill to provide for their registration and inspection was postponed from February 24th to February 25th. The bill was introduced by Mr. Gerald Hurst, who, on February 23rd, attended a meeting of the Medical Committee of the House of Commons, which had been called to hear from him an explanation of the measure. Mr. J. P. Rawlinson, K.C., was also invited to attend this meeting.

**National Insurance.**—Mr. Hayday, on February 24th, asked the Prime Minister whether he was prepared to recommend the extension of the terms of reference of the Royal Commission on National Health Insurance. Mr. Baldwin replied that the Government did not propose to extend the terms of reference of the Royal Commission constituted to deal with the particular questions of national health insurance. Mr. Hayday also asked Mr. Baldwin whether as an alternative he would set up a separate commission with a view to a comprehensive inquiry into all forms of social insurance, and into the possibilities of fuller co-ordination. Mr. Baldwin referred Mr. Hayday to replies given on February 16th, which announced that the inquiries promised by the King's Speech into the "all-in" scheme of insurance were proceeding and that no statement was yet possible.

## Notes in Brief.

In any revision of the Milk (Special Designations) Order the Minister of Health will consider enforcing the use of coloured labels to indicate the grades of milk.

The Minister of Pensions denies that there are general complaints about the periods of waiting undergone by men attending medical boards for "reboarding."

The records of the Pensions Appeal Tribunal do not show the number of appeals for pensions made during 1924 by men suffering from tuberculosis.

Approximately 450,000 final pensions awards have been made since January, 1922, 46 per cent. of them for injuries.

The Home Secretary has asked for fuller information in regard to a request from the Labour benches that "burstis" should be added to "miner's heat-knee" in the schedule of industrial diseases.

Returns in 1923 from education authorities in England and Wales show about 30,000 educable mentally defective children, and about 106,000 physically defective children, including about 49,000 classed as "delicate." About 11,000 mentally defective and about 36,500 physically defective children are attending public elementary schools.

The Minister of Health does not recommend local authorities to adopt generally the proposal to erect flats with cubicle rooms for large families.

Mr. Neville Chamberlain maintains the decision of previous Ministers of Health that officials of his Ministry should not serve on local authorities.

In 1923 statutory declarations of conscientious objection to vaccination were received in respect of 284,551 children.

The Government contemplates a Smoke Abatement Bill, but fears it cannot be introduced this year.

Information on the number of Poor Law medical officers in England and Wales is not available, nor on their salaries. The approximate total remuneration of Poor Law medical officers, dispensers, and nurses in 1922-23 was £1,900,000.

In 1914 the number of bodies removed from Poor Law institutions to medical schools in England and Wales for the purposes of dissection was 301, and in 1923 388.

In the year 1924 approximately £11,700,000 was paid by the workers for national health insurance, £12,700,000 by the employers, and £6,800,000 by the State.

Some 400,000 children in England and Wales leave school each year at the age of 14. The Government is prepared to introduce this session legislation authorizing local authorities to compel unemployed children between 14 and 16 to attend continuation centres.

The Government will not agree to allow the removal of the bodies of those fallen in the great war from abroad to this country.

The Under Secretary of State for India stated that the Government of Bombay was considering the question of the administration of opium to children. According to official statistics, infant mortality in Bombay during 1921 was not 666 per 1,000 as had been suggested, but 178.11 per 1,000.

The Government of India and the London Customs have been asked to report on the export of monkeys from India to Germany and this country.

## Correspondence.

### THE POSSIBILITIES OF EXPLORATORY THORACOTOMY.

SIR,—Professor Gask, in his very interesting article (February 21st, p. 343), does such scanty justice to the contributions of British civil surgeons to the surgery of the chest some decades before the outbreak of the war that some brief epitome of its evolution appears desirable. Your leading article upon the same subject offers some compensation, as the writer has apprehended clearly the real significance of Macewen's operation in 1897. The successful removal of a tuberculous lung was not the essential feature of his work—as might be gathered from a perusal of Professor Gask's article—but that he had opened the chest to its fullest extent to enable him to do so without respiratory embarrassment of a disconcerting degree. This free opening was made deliberately and with full confidence based upon the teachings of Lord Kelvin (Sir William Thomson as he was then), who had proved conclusively that lungs would not collapse under the direct influence of atmospheric pressure when the human thorax had been opened. Macewen showed this patient in good health at the International Congress of Medicine, London, 1913, and again expounded the physical principles enunciated by Lord Kelvin.

Those of us who were familiar with this work and with the work of other British surgeons who had followed Macewen's lead were merely amazed that pressure cabinets of the types of Sauerbruch, Willy Meyer, and Tuffier should be deemed worthy of anything more than a mere passing notice. By the time that they had been invented the problem of chest surgery had long passed the stage of being a problem of lung collapse: it had become one merely of control of infection. Within a few years of Macewen's operation, and many years before pressure cabinets had begun their ephemeral existence, Professor A. E. Barker at University College Hospital had operated quite successfully, as far as the physics of the chest were concerned, upon cases of gangrene of the lung, and during the year 1902, when it was my good fortune to be his house-surgeon, I assisted him at two or three of the operations. From him I learnt the technique of stitching the healthy area of extracted lung to the parietes before excising the enclosed patch of gangrene, so as to limit the spread of infection to the rest of the pleural cavity. In the year 1904 an opportunity came to me of putting Barker's procedure and Macewen's principles into practice; and the following epitome has just been extracted from the official medical notes of the Hospital for Sick Children, Great Ormond Street, of the year 1904:

W. R., a boy aged 10 years, was admitted under the care of Dr. F. G. Penrose on April 6th, 1904. From the fetid expectoration and other signs the diagnosis of gangrene of the lung or lungs was obvious. The patient had been ill for many weeks and his condition was very critical.

Operation was decided upon and carried out on April 7th. Localizing signs of the main area of gangrene were ambiguous, and it was decided to open the right side of the chest first. Nearly the whole of the seventh rib on that side was resected and a digital examination was made of the posterior, lateral, and phrenic surfaces of the lung. As no gross area of disease could be detected the chest was closed on that side, and with full assurance, based on Macewen's teaching, that no collapse of lung need be anticipated, a similar operation was immediately carried out on the left side of the chest. Nearly the whole of the lower lobe of the left lung was easily discovered to be in a gangrenous condition, and after pulling it through the chest wall to enable healthy lung to be stitched to parietes by Barker's method a large mass of it was excised. At no stage of the operation was collapse of the lung or respiratory embarrassment present. The notes state that "after the operation the patient's condition was very good." He became progressively worse, however, and died on April 8th.

At the post-mortem examination no collapse of lungs apart from ordinary post-mortem changes was present: but multiple small abscesses and focal areas of gangrene were scattered throughout both lungs. These latter conditions, present before the operation, but not clearly indicated by physical signs, were the only factors that robbed the operation of success, and not discarded hypotheses about the physical reasons for collapse of lungs.

In a review of "Fifty-five Consecutive Cases of Empyema" (*Lancet*, February, 1909) the mechanics of collapse of lung were elaborated in some detail, and attention was called to the soundness of Macewen's principles by allusion to the

regularity with which lungs expanded on opening the pleural cavity in cases of recent empyema: in fact, as many operators were fully aware, the exuberant resilience of the lung under such conditions became quite frequently an embarrassment to the establishment of effective drainage for the infected cavity.

Finally, decortication of a collapsed lung is no new operation—it was frequently performed by Stansfield Collier at the Great Ormond Street Hospital during the years 1903 to 1908; and the boldness with which the operation was planned and executed was based upon a sound knowledge of Macewen's teaching. During all this bygone period lung abscesses due to foreign bodies were sought for by "exploratory thoracotomies," at a time when radiography was little help in aiding clinical methods to localize their site, and pieces of string and husks of dried grass that had been inhaled were successfully removed when the operator was fortunate enough to localize the abscess. The landmarks of chest surgery were not set up by French, German, or military surgeons of the year 1916! They had been erected long previously by British surgeons and scientists, who were the teachers of my generation and of a generation earlier than mine. Honour to them has long been overdue: to render it in some humble degree is the sole motive of this letter.

Professor Gask has done noble work on the surgery of the chest that has secured him his niche in fame. That other niches are already occupied by pioneer associates of British origin too should not make it any the less acceptable to him.—I am, etc.,

London, W.1, Feb. 22nd.

GEORGE WAUGH.

SIR,—I have been interested in Professor Gask's paper on the possibilities of exploratory thoracotomy. I cannot, however, agree with his view of the position of thoracic surgery at the advent of the great war, for some of us for years before the war had been performing thoracic operations of the kind to which he refers.

Professor Gask mentions that Macewen removed a lung in 1897. I may refer him to the following accounts of cases published by me: (a) A case of successful excision of a portion of the right lung for pulmonary tuberculosis (*Lancet*, July 21st, 1906); (b) the surgical treatment of chronic pleural effusions (*Practitioner*, February, 1911). For more than forty years it has been my practice to drain cases of empyema by means of a double incision with a large tube threaded through; this admits as much air into the pleural cavity as would be admitted by an incision for exploratory purposes. I have performed a very large number of these operations without the aid of any of the costly pressure chambers mentioned by Professor Gask.

Hence it is evident that surgeons before the war were not all imbued with the "widespread, though ill founded, belief that on the opening of one pleural cavity under ordinary atmospheric pressure not only one lung, but both lungs, would collapse and the patient die of asphyxia."—I am, etc.,

Kiddleminster, Feb. 23rd.

J. LIONEL STRETTON.

### CANCER OF OESOPHAGUS.

SIR,—May I make a plea for earlier gastrostomy in the treatment of cancer of the oesophagus? Many cases present themselves in this district when the disease is already somewhat advanced. If in these conditions oesophagoscopy is performed, not only is the ulcerated constriction seen to be irritated by endeavours to pass food, but it bleeds easily, is oedematous, and generally bathed in foul mucus, rendering any dilatation or the passage of tubes difficult, and, when the trouble is situated just behind the aortic arch, very hazardous.

The result of gastrostomy is very marked. After ten days or a fortnight much of the irritability disappears, and manipulations through the oesophagoscope are thus rendered more easy of performance. Particularly did I notice this in the case of a lady with a malignant stricture thirteen inches distant from the teeth, into which I endeavoured to pass a radium cylinder. The attempt failed owing to free bleeding. Gastrostomy was then performed under local anaesthesia, and ten days subsequently

it was found quite easy to insert the radium, the stricture having been rested and bleeding being absent. Senn's method of gastrostomy is easy of performance, is readily done with a local injection of novocain and adrenaline, and causes no shock and very little discomfort to the patient; feeding can immediately be commenced, the patient rapidly gains in weight and strength, and the rest given to the stricture renders further treatment considerably easier. And, after all, is it not carrying out an important surgical principle of giving rest to a diseased structure, and analogous to colostomy in rectal carcinoma?—I am, etc.,

Portsmouth, Feb. 16th.

C. A. SCOTT RIDOUT.

### THE INFECTIVITY OF SMALL-POX IN THE INCUBATION STAGE.

SIR,—It seems to me highly important that the general statement contained in Dr. Rolleston's book on *Acute Infectious Diseases* that "the small-pox patient is infectious in all stages of the disease, even in the incubation period, before any symptoms have appeared," should be fully considered.

Quotations from foreign publications to the effect that patients in the incubation stage may be infectious do not seem to me to be final. More convincing evidence for such a heterodox view is called for. Our administrative procedures are built up on the contrary hypothesis.

1. When a person has been in known contact with a small-pox patient it is regarded as sufficient that that person should be visited on the twelfth day after the appearance of the rash on the patient and for about six days afterwards. My experience of many hundreds of cases of small-pox has never led me to regard this as a defective procedure. In other words, I have never had reason to suppose that the infection could have been contracted at a time prior to the appearance of the rash.

2. The course recommended officially by the Ministry of Health, and adopted, I believe, in most areas, of not taking any steps for the isolation of contacts, would lead to disaster, if it be admitted that the ordinary case of small-pox is infectious in the incubation stage.

3. If the twelve days' incubation period is really an infectious period, it would be impossible for any local authority to cope with an epidemic of small-pox, except by general vaccination; if every patient were a medium of infection for twelve days before any symptom of illness, no policy of isolation could be successful; yet in practice—with adequate staff and systematic following up of contacts—small-pox is one of the most easily controlled of the infectious diseases, in spite of the disregard of vaccination and in spite of the anomalously mild character of the present epidemic.—I am, etc.,

Coventry, Feb. 17th.

E. H. SNELL.

### THE HYPOTONIC (FLABBY) CHILD.

SIR,—Dr. Donald Paterson's paper (February 14th, p. 301) on the hypotonic child brings forward points of great interest and importance. He rightly points out that a large proportion of the children attending an out-patient clinic present the characteristics of this type of child, and it is from amongst them that many of the rheumatic, cardiac, tuberculous, orthopaedic, and eye cases are recruited. Whilst the muscular hypotonia is possibly the most striking defect, yet with the hypotonia there almost always exists a toneless state of the other systems, especially the circulatory and the vasomotor, in the nervous tissues, and in the mucous surfaces with their underlying lymph nodes.

In discussing the factors at work in the production of this health defect Dr. Paterson refers to a paper of mine (*Lancet*, August 2nd, 1924) with reference to the "debilitated child," and quotes me as stating that a toxæmia plays an important part in the production of this physical defect. This is not quite as I expressed it. The child discussed by me was the child of school age rather than the child between the ages 2 and 7 discussed by Dr. Paterson, and although I used the word "hypotonia" in relationship to the muscular system, yet the words "toneless" and "wasted" are perhaps more

applicable to the age period I was considering than the hypotonia of the flabby younger child. I think, however, it only a question of degree, and that the same etiological factors are at work in the case of both age periods. I gave it as my opinion that there are two main factors—a dietetic and a toxic—to be considered, the former bring the cause of the toneless condition, and the latter the cause of the numerous superadded symptoms, such as the limb pains, headaches, nervous irritability, and glandular hyperplasia. I am therefore in agreement with Dr. Paterson in believing that the hypotonia has a dietetic origin; and while he would make wast of muscular exercise an additional cause—and no doubt this and other hygienic defects are contributory factors—yet I hope and believe that he will agree that the dietetic is far and away the most important. It appears to me that Dr. Cameron (*BRITISH MEDICAL JOURNAL*, November 24th, 1923) was referring to this same type of case in his paper to which Dr. Paterson also refers, and also Dr. Lapar (*BRITISH MEDICAL JOURNAL*, July 2nd, 1921) when he drew attention to certain problems in connexion with the toxic states of childhood.

I suggest that all of us have attempted to draw attention to, and give reasons for, certain very common defects in health which in the past have been neglected in favour of what one may call the "graveyard conditions," and the rare types of case which, while of interest to the few, are of little importance as compared to these health defects which are the forerunners of most of the common diseases of childhood, and indeed of adult life. I hope, therefore, that Dr. Paterson's contribution, and Dr. Lucy Wills's report upon her investigation of this type of case published in the same issue, may stimulate further study and draw attention to a subject of first importance from a national standpoint.—I am, etc.,

Leeds, Feb. 16th.

C. W. YINING.

SIR,—Under this heading Dr. Donald Paterson (*BRITISH MEDICAL JOURNAL*, February 14th, 1925) unwittingly gives an accurate though incomplete account of chronic intestinal stasis as seen in children. His observations on the causes of the condition prove that he is, in fact, describing stasis. The lines of treatment which he favours include some of those most useful in stasis. His treatment would be even more remarkable in its results were it preceded by a search (clinical, radiological, bacteriological, and chemical) for evidences of stasis. Radiological observations might disclose the need for surgery, and in every case colloidal kaolin (kaylene) and liquid paraffin should be prescribed.—I am, etc.,

London, W.1, Feb. 19th.

A. C. JORDAN.

### TESTS FOR DRUNKENNESS.

SIR,—The letter in your issue of January 31st (p. 240) by Sir Charles A. Ballance and Dr. Maurice Cassidy comes at a very opportune time.

With regard to the reply of Sir James Purves-Stewart of February 7th (p. 282), may I observe that there is, unfortunately for the medical profession, another side to the question? What are the magistrates on the bench to conclude when, on the one hand, they hear several police constables, whom they know to be thoroughly reliable officers, as well as independent lay witnesses, supported by the police surgeon, probably a man of great experience and integrity, state on oath that the defendant was drunk (as Sir Francis Champneys happily suggests, "the worse for drink"); on the other hand, on the part of the defendant, if a substantial person, medical men of eminence can be found to take oath and say that he was perfectly sober?

It must not be presumed that because the court in the circumstances does not record a conviction that the magistrates have any real doubt in their minds on which side the truth lies.

In conclusion, I give this for a moral. A few years ago the certificate of a duly qualified medical man was always accepted in any court of law. At the present time no court will accept a medical certificate.—I am, etc.,

Here, Feb. 18th.

H. H. TAYLOR, J.P., F.R.C.S.

SIR,—To those interested in tests for drunkenness the following facts may appeal.

When I was appointed a police surgeon I had been in active practice for ten years and considered myself perfectly capable of diagnosing drunkenness; but my self-reliance was misplaced, as two instances among many will show.

I was called to one of my stations to see a man who denied being drunk, and in furtherance of my scheme of investigation I talked with him for probably half an hour, during which the usual tests were applied. I then said to the inspector, "I do not think this man is drunk." On this the officer told the prisoner that "as the doctor said he was sober he might go." Much pleased with this result he relaxed his tension (which I had failed to estimate), fell down the station steps, and came to rest in a confused heap on the pavement. Much to my disgust I had to withdraw all I had said and certify him.

On another occasion an alleged "drunk," similarly allowed to go, fell into the hands of another officer, who knew nothing of the previous charge, and was brought in again by him. After years of experience I got to know, although my nephew, Dr. George Grant, required some convincing in the matter, and he got his lesson in this way:

Going with me to the station one evening he disagreed, in somewhat indignant terms, with my diagnosis of drunkenness in regard to a prisoner. However, I certified and told the police to put the man in a cell. I then took my nephew for a short walk, and on our return to the station, probably in a quarter of an hour, we went to visit the accused. He was asleep on the wooden bench, breathing stertorously; he was awakened with difficulty and was unable to stand when pulled up. In addition, his confusion of ideas was so obvious, and the alcoholic odour in the cell so marked, that when I said to the doctor "Is that man drunk or sober?" he replied, as other medical men similarly instructed have replied—"Drunk."

*Experientia docet.*—I am, etc.,

London, E.C., Feb. 18th.

GRAHAM GRANT.

#### ISOLATION HOSPITALS FOR SCARLET FEVER.

SIR,—Dr. Robert Watson's interesting letter is little help as a reply to my question. Purposely I said nothing on the well worn topic of the failings of isolation hospitals in respect to scarlet fever.

Everyone with experience is agreed that individual cases—with or without inunction treatment—would best be treated at home; but practically the difficulties are so great that the balance has inclined inevitably to the removal of the patient to hospital. I could point to pages in old annual reports, especially twenty to twenty-five years ago, where the whole question was discussed. Faith in the inunction treatment is not sufficiently firm and universal to satisfy the public, and hardship is very great when a case occurs in a small shop, such as a stationer's, or in a house used as a day school for small children. We have committed our generation to hospital isolation, and the important thing is to make the best of it. I now believe that the want of protected exercising space is one of the weakest points in the administration of these hospitals, and my query was whether, with building prices as they are, it would be justifiable to insist upon extra expenditure in this direction. Dr. Watson calls this "a call for 'more stately mansions' in the isolation camp." I still hope that some correspondent may see my point and give the help of his opinion.—I am, etc.,

Bromsgrove, Feb. 21st.

H. CAMERON KIDD.

\* \* We hope that we shall not be asked to allow this correspondence to drift into a discussion of the value of inunction in scarlet fever.

#### THE LAW OF THE ROAD.

SIR,—It would seem that many writers on traffic dangers are not conversant with the law of the road. Under the Highway Act of 1835, the driver of every cart, carriage, or other vehicle is bound to keep to the left, or near, side of the road when meeting another cart, etc. Mark carefully it is *side*, not *half*, to which the driver has to keep. During the many years (over sixty) I have been a driver of different vehicles I have even found stipendiary magistrates ignorant of this law. The penalty is—for an owner driver, not exceeding £10; for a hired driver, not exceeding £5.—I am, etc.,

Bury, Feb. 21st.

JAMES HOLMES.

SIR,—The suggestion of Dr. Charles Buttar—the "right-hand" rule—has sense and simplicity to recommend it, and at sea, applied as the "starboard" rule, has the experience and tradition of the sailors to speak for it.

The executive of the British Medical Association, entitled to speak with authority on behalf of a very large body of motorists, and also in the interests of public health, might well bring this suggestion before the Minister of Transport, and the thing is done and done quickly.

Dr. Buttar's article tells the old sad story of the lonely furrow, which apparently he has fruitlessly ploughed for many years.—I am, etc.,

London, S.W.1, Feb. 23rd.

REDMOND ROCHE.

#### A JOURNALISTIC INDISCRETION.

SIR,—I associate myself entirely with Dr. Drury Pennington's statement to you that neither he nor any of his colleagues knew that the recent series of articles in the *Daily News*, dealing with 86, Brook Street, was being prepared or written. It was, indeed, part of the scheme of the articles that they should be the outcome of visits paid on precisely the same terms and under the same conditions as would be accorded to an ordinary member of the public. For that reason, obviously, we did not disclose to those conducting the establishment the fact that they were dealing with a representative of the *Daily News*.

I confess, however, that I do not see how you justify the use of your headline, "A Journalistic Indiscretion." Surely it is a matter of legitimate enterprise for a newspaper to make an actual and genuine test of a scheme which is so important from the public point of view.

I hope, in justice to the *Daily News*, you will publish this letter.—I am, etc.,

London, E.C.4, Feb. 21st.

J. HUGH JONES,  
Managing Editor.

#### THE DUODENAL FLORA IN ACHLORHYDRIA.

SIR,—May I ask you to publish a small correction of your report (p. 360) of my few remarks concerning the duodenal flora in achlorhydria? In cases showing marked anaemia I have certainly been impressed by the large number of living streptococci recoverable from the duodenum and by the fact that these cultures so frequently contain strains producing haemolysin. It is impossible, of course, to detect the haemolytic varieties in direct films.—I am, etc.,

Wimbledon, Feb. 21st.

F. A. KNOTT.

#### ANAESTHETICS FOR REGISTERED DENTISTS.

SIR,—From letters which I have received I gather that some practitioners are in doubt as to the bearing of the following paragraph in the Warning Notice issued by the General Medical Council:

"5. Association with Unqualified Persons.

"Any registered medical practitioner who, either by administering anaesthetics or otherwise, assists an unqualified or unregistered person to attend, treat, or perform an operation upon any other person, in respect of matters requiring professional discretion or skill, will be liable on proof of the facts to have his name erased from the *Medical Register*."

I am directed to say that this warning does not apply to any person whose name appears upon the *Dentists Register*, whether so entered in virtue of a diploma or under the Dentists Act, 1921. A registered medical practitioner is entirely at liberty to give an anaesthetic for such a dentist.

In the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of January 5th, 1924 (p. 23), there was a paragraph relating to this matter, in which it was stated:

"In these circumstances medical practitioners need have no hesitation in administering anaesthetics for a dentist without diploma when asked to do so, once they are satisfied that he is actually on the *Dentists Register*. There is, in fact, no legal justification for refusing to do so."

I think it might be helpful if the attention of medical practitioners was again drawn to their position in regard to this matter.—I am, etc.,

London, W.1, Feb. 24th.

NORMAN C. KING,  
Registrar, General Medical Council.

## Obituary.

### THE RIGHT HON. SIR T. CLIFFORD ALLBUTT, K.C.B., M.D., LL.D., D.Sc., F.R.C.P., F.R.S.,

Regius Professor of Physic in the University of Cambridge;  
President of the British Medical Association, 1916-21.

(With Portrait by J. Palmer Clarke, Cambridge.)

THE medical profession has learnt with sorrow that Sir Clifford Allbutt died suddenly in the early morning of Sunday, February 22nd, at St. Radegund's, Cambridge, in his 89th year. His bodily powers had failed somewhat in recent months, but his mind was clear and active to the last day of his life. He woke up, and after a severe attack of breathlessness passed away in about ten minutes. In him British Medicine loses a great and venerated leader, full of years and honours, a scholar-physician and a great-hearted gentleman.

Thomas Clifford Allbutt was the son of the Rev. Thomas Allbutt, at one time vicar of Dewsbury, Yorkshire, and later rector of Debach-cum-Boulge in Suffolk, who married Marianne, daughter of John Wooler of Dewsbury, and was a friend of the naturalist Waterton. He was born at Dewsbury on July 20th, 1836. His early education was received by private tuition at Ryde, Isle of Wight, and his school days were passed at St. Peter's, York, then under the headmastership of Archdeacon Hey, the entomologist.

He entered Gonville and Caius College, Cambridge, in 1856, gaining a classical scholarship in his first year and others subsequently. About that time the Cambridge Medical Faculty was waking from its long sleep, and as many as six medical students were in residence together; they had to complete their course in Arts before commencing medicine. Natural science was already making enormous strides in the University. Allbutt graduated B.A. in 1859, and in the next year was placed in the first class in the Natural Sciences Tripos with distinction in physiology. His clinical education was received at St. George's Hospital, London, and he also studied for a time at Paris. He took the degree of M.B. at Cambridge in 1861, the M.A. in 1867, and proceeded M.D. in 1869. While at St. George's Hospital he formed a friendship with Dr. J. A. Lockhart Clarke, the anatomist and pathologist, and George Henry Lewes. The latter was then devoting a good deal of his time to preparing the chapter on the anatomy of the nervous system for his *Physical Basis of Mind*. Lockhart Clarke, although he had been qualified for several years, was taking out hospital work again at St. George's Hospital for the M.R.C.S. diploma at the time Allbutt was studying there. His microscopical work on the nervous system, which he carried out by a new method that revolutionized histological research, interested Allbutt and influenced him towards a similar line of study, and he published some of his earliest papers on diseases of the nervous system in the *St. George's Hospital Reports* and in the *Transactions of the Pathological Society*. He maintained his friendship with Lewes until his death in 1878, and George Eliot, writing of her tour in Yorkshire with Lewes in 1868, says: "We went on from Leeds to Bolton. Our visit to Yorkshire was extremely agreeable. Our host, Dr. Allbutt, is a good, clever, graceful man, enough to enable one to be cheerful under the horrible smoke of ugly Leeds. . . ." We also read of Allbutt visiting George Eliot and Lewes at their Witley home at a later date. There is good evidence that he was the original of Lydgate in George Eliot's *Middlemarch*.

In 1862 he was appointed honorary physician to the Leeds House of Recovery, and in 1864 honorary assistant physician to the Leeds General Infirmary, Dispensary, and Fever Hospital, and also lecturer in the practice of physic in the Yorkshire College, Leeds. Two years later he began to lecture in anatomy as well. He remained on the active staff of the Leeds General Infirmary until 1884, when, in accordance with the rules of the institution at that time, he gave up the charge of beds and joined the consulting staff. He continued in consulting practice until 1889, when he was appointed a Commissioner in Lunacy, and held this post for three years until his appointment as Regius Professor

of Physic in the University of Cambridge and his election to a Fellowship at Caius College.

He became a Member of the Royal College of Physicians of London in 1878, and a Fellow in 1883. He was an examiner for the College in 1899, censor in 1905-6, and member of the council in 1906-7. In 1900 he delivered the Harveian Oration before the College, the Gombstonian Lectures in 1884, and the FitzPatrick Lectures in 1909-10. He was awarded the Moxon Medal in 1921.

His election in 1892 to succeed Sir George Paget in the Regius Chair of Physic at Cambridge University was generally applauded as likely to result in advantage to the University and to import into the region of medicine there a certain element of freshness and originality which could not be too highly rated. How fully that expectation was fulfilled is now a matter of history. Concurrently with his election to the professorship he was appointed physician to Addenbrooke's Hospital.

Allbutt's professional life naturally falls into two distinct periods—his Leeds consulting life, and his Cambridge academical work with an interregnum of lunacy commissionership.

At Leeds he lived the fullest possible life of a consulting hospital physician, clinical observer, and teacher. For many years his practice there was phenomenally big for a provincial consultant, and, in addition, he had his teaching. In his earlier years he was actively engaged in clinical research and writing papers, diseases of the nervous system and the effect of overstress on the heart chiefly interesting him. He was also collecting material for this work on the use of the ophthalmoscope in medicine (1871), and in the preparation of this he received much help from Dr. (afterwards Sir James) Crichton-Browne, who was then medical superintendent of the West Riding Asylum, and who had, in the face of considerable opposition, established a research laboratory there. This had for its title *The Use of the Ophthalmoscope in Diseases of the Nervous System and of the Kidneys and also in certain other General Disorders*. The book was dedicated to Hughlings Jackson in a prefatory letter in which Allbutt pointed out that they both had begun about the same time to use the instrument in the investigation of cerebral diseases, and paid a tribute of respect to Hughlings Jackson's friendship and help. Allbutt had received his first ideas of the probable value of the ophthalmoscope in the diagnosis of cerebral disease from Dr. Ogle when he was at St. George's Hospital, and he had continued his work on the subject at Leeds. In this book Allbutt traversed the whole field of the knowledge of the time, and gave his own experience, whether as original observations or in support of those of other observers. Perhaps the most original chapter is on the condition of the disc in mental diseases, especially in general paralysis of the insane. He carried out a series of observations in this disease, and discussed the atrophy of the discs which he found in the *Medico-Chirurgical Transactions* in 1868. He afterwards learnt that von Graefe and others had previously noticed similar appearances in general paralysis, but from a less extensive series of cases. Many of his clinical observations were confirmed by subsequent microscopic observations. He also described the ophthalmoscopic appearances in a large number of cases of tuberculous meningitis, and pointed out that the neuritis in these cases might disappear with recovery from the general disease. It was he who suggested the use of the term "choked disc," now generally used in English ophthalmology, instead of von Graefe's *Stauungs-pupille*, for the swollen disc met with in many cases of intracranial disease. Only one edition of the book was published; it was succeeded by the fuller and more extensively illustrated work of Gowers on the same subject, published eight years later.

In 1873 he read before the Royal Society a paper on the effect of exercise on the bodily temperature (*Journ. Anat. and Phys.*, 1873, vol. vii). He had been for some years previously engaged in the study of the temperature of the body in health and disease, and had published his results in various papers. He felt that such a study could only find a satisfactory basis in a knowledge of the temperature of the healthy body, and he knew of no observations on the effects of hard and prolonged exercise on the body. Such

Clifford Hillier

# SIR CLIFFORD ALLBUTT.

FEB. 28, 1925]

observations he, however, afterwards heard had been made during ascents of Mont Blanc in 1869. His own investigation was also carried out while climbing in Switzerland in the following year (1870). His conclusions were that the normal effect of exercise was to increase temperature slightly during the day, and to favour the early occurrence of the evening's fall when the day's work was done. When the day's work continued to 6.30 or 7 the fall was postponed until the time of rest, when it quickly set in.

Here we may take the opportunity of mentioning that one of Allbutt's chief recreations as a young man and in early middle life was climbing in Switzerland, a difficult art in which he acquired great skill. He was a member of the Alpine Club. As a boy, and indeed throughout the whole of his life, he was very fond of the Lake Country, and his last published letter, which appeared in the *Times* a week or two ago, was a plea for the preservation of the simple beauties of Grasmere. He enjoyed, indeed, walking anywhere, and was one of the band of Sunday Tramps organized by Leslie Stephen. He took to cycling also in the early days of that recreation, and kept it up till old age; in fact, a few years ago he met with a rather awkward accident while cycling in Cambridge which laid him up for several weeks.

Allbutt published many other important papers on various subjects in the medical journals, but as he rewrote and amplified the most valuable of them for the great medical work with which his name will always be so honourably associated—of which he was editor and driving force—we may refer to them in connexion with this work. The first volume of the *System of Medicine* appeared in 1896 and the last, or eighth, in 1899. Allbutt contributed articles to all of the volumes except the first. Those which he wrote were on grain and mushroom poisoning, opium and other intoxications, mountain sickness, chlorosis, neuroses of the stomach, dilatation of the stomach, scrofula (with Mr. Pridgin Teale), functional disease of the heart, mechanical strain of the heart (title changed to overstress of the heart in the second edition), diseases of the aortic area of the heart, adiposis dolorosa, senile paraplegia, and neurasthenia. These were subjects on which with his large practical experience he could write with authority and illumination, and some of them—especially those on the stomach and heart, and on neurasthenia—were as good and useful as any articles in the whole *System*. The labour involved in the editing of the *System*, which included its planning, the choice of subjects and writers, and the cross-referencing in the articles, even with the unofficial help of Dr. (now Sir Humphry) Rolleston, must have been enormous. The many writers who contributed articles to the *System* were chosen for their special experience in the subjects about which they wrote, and although there was some unevenness in the value of the articles, as must necessarily be the product of a much needed work of reference of the first order. Its reception by the profession was such that a new edition was soon called for, but as considerable changes and additions were found desirable it was not until 1905 that its first volume could be published.

In producing this second edition Allbutt had the very active and valuable, and this time official, assistance of Dr. Rolleston in the editorial work. The last volume of the new edition was published in 1912. It was more than a mere revision. Inequalities in the first edition were corrected; many new articles were added, and those which required it were brought up to standard form by judicious revision; considerable rearrangement in the order of the articles was also carried out. The bibliography, which is such a valuable feature of the *System*, was carefully revised and the indexes elaborately and accurately drawn out by Dr. A. J. Jex-Blake. This is work which if ill done mars the accuracy of this subediting work was very commendable. In the case of Allbutt and Rolleston's *System* were increased to nine, and as two of these consisted of two parts, each a separate book, the whole work ran to eleven large volumes. Allbutt himself, besides refreshing his original articles, contributed a new one, with the collaboration of the late Dr. J. F. Payne, on the history of

medicine. It is an excellent example of the historical type of article which he wrote so well and with so much pleasure. The *System*, especially the second edition of it, is one that the medical literature of any language could be proud of, and must stand as a worthy monument to its originator and first editor. We may refer more fully to some of his more important articles in the *System*.

Allbutt's opportunities for studying the effects of over-stress on the heart—first, among the athletes at Cambridge, and, secondly, among the manual workers of the Leeds and Bridge University—were unusually wide, including as they did two different types of hard muscular labour, forced and voluntary, at different ages and under vastly different conditions of feeding and training. He divided his subject into three parts—namely, static and permanent disease of the heart and arteries, due or attributed to extraordinary effort; dynamic and almost insensible spoiling of the vascular system due, really or apparently, to the wear of hard muscular labour during long terms of years, especially when the freshness of youth is past. In all three series the problem is complicated by various obscure contributing influences; the first division he dealt with chiefly under the separate heading of diseases of the aortic area; the third was more concerned with diseases of the arteries, and the second formed the main part of this section on over-stress of the heart. He defined his subject as being the dynamic change in persons of otherwise healthy body, who by single or persistent exertion may have urged muscular effort to degrees menacing or hurtful to the organs of the circulation, or in whom efforts, if less severe, have told upon a vascular system already somewhat impaired by other causes. The article is a very full account of the subject as it is met with in school and adult life, due credit being paid to the work of other observers in the same field, especially to Dr. R. W. Michel of Cambridge (who was killed in action in 1916). He concluded his long article with the opinion, founded on thirty years of close observation of heart stress, "that the importance of muscular effort as a factor in cardiac injury has been much exaggerated. In the sound adult organism the effects of physical stress upon the heart are promptly counteracted by equilibrating machinery, and especially by large expansion of muscular and pulmonary areas."

The section on diseases of the aortic area of the heart is also very full and authoritative. The most interesting cause to him is apparently overstress. In 1870 he wrote that such acute strains as mountain climbing and the like were apt to tell rather upon the right side of the heart, the chronic effects of years of labour on its left side. Broadly speaking, he always maintained this opinion, but he was well aware that an aortic valve might give way as the result of overstress with consequent disastrous effects on the left heart muscle. The subject of neurasthenia also was one on which he could write with much experience and authority. His article on it in vol. viii of the second edition of the *System* is one of the most useful and practical in the whole work. It occupies sixty pages, and is a most illuminating, thorough, scientific, and instructive account of a condition which in its varied manifestations presents so many difficulties in diagnosis and treatment, and provides the basis for so much argument in law courts.

The effect of exercise on the blood pressure was also a subject that interested him greatly, and to which he devoted a considerable amount of investigation. He found, as did other observers also, that muscular exercise tends to the long run not to raise, but even to reduce, the mean arterial pressure of the twenty-four hours. On the other hand, the blood pressure of men who, as athletic habits are laid aside, lead sedentary lives without denying themselves at least as great an abundance of food, is prone to rise. Under the name of senile plethora or "hyperpirosis," as he called the condition (*Med.-Chir. Trans.*, London, 1903, vol. 86), he described irregular and indefinite variations in health in people beyond middle life which were associated with persistent elevation of the arterial blood pressure. This condition may exist for years, especially if untreated, and may never be associated with renal disease, although both conditions might arise from the same cause. The patients complain of insomnia, cerebral confusion, despond-

ency, and nervousness, but are not necessarily dangerously ill, especially if tension-lowering remedies be prescribed. He recurrd to the subject in his contribution to the important discussion on blood pressure in relation to disease, held in the Section of Medicine at the Annual Meeting of the British Medical Association at Toronto in 1906, when he followed the late Professor Gibson of Edinburgh and the late Sir William Broadbent. His paper, which was published in the *BRITISH MEDICAL JOURNAL* of October 20th, 1906 (p. 1004), contains a summary of his views and a classification of the cases founded on clinical observation.

No one but a man of methodical habit and business capacity could edit successfully such a large work as the *System*, and write so many articles and papers or prepare so many addresses, as the Regius Professor of Physic did. And he was such a man of system and method, constantly watching for any fact, opinion, clinical or scientific observation, or case that interested him, that whenever he came across anything of this nature he made a careful note of it, with the source from which it was obtained and any comment that struck him. This he filed away, either to swell the number of other notes already there, or to form the nucleus of some new batch. It was by such constant vigilance and daily systematic collection of notes that he was able to contribute so much to medical literature. A batch of notes on one subject would form the nucleus of an article, and he wrote them up with a literary skill that made all his papers a delight to read. He had a very extensive command of good English and a wide knowledge of general literature, from which he would draw apposite quotations as sidelights to the subject proper. Aiming at a high standard of writing himself, he desired others to do likewise.

Allbutt was a charming speaker; at first hearing his style seemed loose, but the construction of his sentences, if sometimes complex, was always rigidly correct, and he never failed to convey his meaning with clearness and force. His style, indeed, reflected his mind—full, eager, impetuous, but disciplined. Allbutt once described to a friend how his book *Notes on the Composition of Scientific Papers* came into existence, and the story is characteristic of his sanguine temperament and of his thoroughness. It was his duty as Regius Professor—a duty he most religiously fulfilled—to read a great many theses, and not infrequently his soul was vexed by faults of literary expression and logical arrangement of ideas. On one winter afternoon, when the evil was borne in upon him, he turned to the desk in the big room in which he worked, and picking up half a sheet of notepaper prepared to set out on it certain aphorisms or guiding principles. He failed to get all he had to say on the half sheet of notepaper that day, and turning back to the subject at odd times the notes gradually grew into a book, which may be perused with advantage, not only by the writers of theses and medical articles, but by all who aspire to write on scientific subjects. It appeared first in 1904, and was reissued in 1905; the third edition, long called for, was delayed by the war and other preoccupations until 1923.

The publication fifty-four years ago of his first book, *The Ophthalmoscope in Medicine*, not only taught the profession the value of a new means of investigating disease, but revealed a new clinical observer of the highest promise. It was at this stage of his career that he invented the short clinical thermometer. Realizing the impracticability of the cumbersome instrument, some ten inches long, which was then little more than a curiosity of hospital wards, Allbutt in 1867 instructed a Leeds firm to make him a series of experimental thermometers, with a chamber above the bulb, and managed to reduce the length of the tube to three inches. The pocket clinical thermometer thus devised by him came rapidly into general use. It was a mechanical improvement that greatly helped medical men in their daily work, and the need for it could only have occurred to a physician actively engaged in clinical practice. To those days, too, as already indicated, belonged his epoch-making researches into the cause of certain diseases of the brain and spinal cord, and into the effects of strain on the heart and great vessels. The high expectations built on the originality and the wide grasp of essential principles displayed during this early period were more than justified.

Besides many shorter contributions to the history of medicine, Allbutt published in 1901 *Science and Medical Thought*, and in 1905 a collection of lectures delivered in America entitled *The Historical Relations of Medicine and Surgery*. In 1921 appeared *Greek Medicine in Rome*—an expansion of his FitzPatrick Lectures, together with other historical essays. This monumental work he dedicated most appropriately to Sir Norman Moore. It contained abundant evidence that the veteran Regius Professor of Physic had never lost his delight in classical studies, for it was as a classical scholar of Caius College that he began his Cambridge career. The book was regarded by competent authorities as the crown of his labours as a medical historian.

Allbutt was elected a Fellow of the Royal Society in 1880, and served on the council for two periods, 1885-88 and 1914-16, when he was also vice-president. The honours conferred on him by scientific and learned bodies at home and abroad form an imposing list. His honorary degrees included the D.Sc. of Oxford, Manchester, and Leeds; the M.D. of Dublin; the LL.D. of Glasgow, McGill, Toronto, St. Andrews, and Durham, and of his own University. He was a Fellow of the Linnean Society and of the Society of Antiquaries; an honorary member of the American Association of Physicians and of the American Academy of Arts and Sciences; an honorary Fellow of the Royal College of Physicians of Ireland, the New York Academy of Medicine, and the Royal Society of Medicine. He was a member of the Hellenic Society, and had served for some years on the Managing Committee of the British School at Athens. In 1907 he was created K.C.B., and in 1920, during the Annual Meeting of the British Medical Association over which he presided at Cambridge, he was made a Privy Counsellor of Great Britain. He was an original member of the Medical Research Council, and from 1908 to 1918 represented the University of Cambridge upon the General Medical Council. The King Edward VII Sanatorium at Midhurst, the Belgrave Hospital for Children, and the Mount Vernon Hospital for Consumption, each counted him among its consulting physicians.

Sir Clifford Allbutt's services to the British Medical Association cover a period of more than fifty-five years. At the Annual Meeting at Leeds in 1869 he was Secretary of the Section of Medicine; he was Vice-President of that Section in 1876 at Bath; President in 1882 at Worcester, when the Association celebrated its jubilee in its native city; and President of the Section again in 1889, when the Association met once more at Leeds. In his Presidential Address to the Section of Medicine in 1882, and again when he delivered the Address in Medicine at the Glasgow meeting of 1888, he pleaded for a broader outlook and demanded that inquiries into the nature and causes of disease should not be limited to man, or even to the animal kingdom, but should extend to plants, which presented in a simpler form problems not dissimilar. At first his was a solitary voice, but he lived long enough to witness the beginning of a realization of his ideals.

When the Association met in 1914 at Aberdeen, on the eve of the war, Sir Clifford was appointed President-Elect. The Annual Meetings were not resumed until 1920, but in 1915 he was reappointed President-Elect; in 1916, a few days after his 80th birthday, he was elected with acclamation President of the Association, and was re-elected year by year until the Annual Meeting of 1921. Thus it came about that Sir Clifford Allbutt held the highest office in the Association for a far longer time than any man had ever held it before, and during that period, notwithstanding the incessant strain of war time—for he was Honorary Colonel Eastern Division R.A.M.C., and did much work in an advisory capacity in many directions—he managed to interest himself in every side of the Association's work, and to attend with great diligence the many meetings to which he was summoned. His long presidency brought him into close and affectionate contact with officers, officials, councillors, committeemen, and representatives. When, a few months after the armistice, a special clinical and scientific meeting of the Association was held in London to discuss and demonstrate the lessons learnt in the war, he opened the proceedings with an illuminating address entitled "The

New Birth of Medicine." In the summer of 1920 the long-deferred Annual Meeting was held at Cambridge. The subject of the Presidential Address was "The University in Medical Research and Practice," but the subject-matter of this singularly suggestive discourse went far, though not unduly far, beyond its title. The Cambridge meeting was a great success; its President, for all his years, seemed ubiquitous, indefatigable, and a source of inspiration to everyone. At this meeting his portrait, by Sir William Orpen, R.A., was given to him, on behalf of an immense number of members of the medical profession. Sir Norman Moore, who made the presentation, aptly described him as a devoted servant of the profession of medicine, deserving a place in the very front rank and side by side with the great ones of the past; one who had never spared himself if he could add to the knowledge of medicine, or stimulate anyone else to add to that knowledge. The portrait now hangs in the Fitzwilliam Museum.\* At the Annual Meeting of 1922 in Glasgow Sir Clifford received the Association's Gold Medal, together with an engrossed testimonial setting out the grounds of the award. This opened with the words: "We delight to honour in you a great physician, a great teacher, and a wise friend in counsel," and ended: "In token of our respect and affection for you as a man, of our admiration for you as a physician and teacher, and of our gratitude to you for the generous spirit in which you gave freely of your time and wisdom to the Association during a period of unexampled strain and difficulty, we ask you to accept at the hands of our President the British Medical Association's Gold Medal for Distinguished Merit." During his period of office as immediate Past-President, Sir Clifford attended regularly the meetings of Council, and he continued to serve the Association as a valued member, and for some time chairman, of the Science Committee. He was throughout his professional life a true friend to the *BRITISH MEDICAL JOURNAL*, helping it in matters great and small with unfailing courtesy and the kindest encouragement. Nor must we forget the powerful support he gave, by pen and by word of mouth, to the insurance practitioners of the country in their long-drawn-out struggle for fair payment and proper professional status.

Sir Clifford Allbutt married in 1869 Susan, daughter of Thomas England of Headingley. They had no children. To Lady Allbutt the sympathy of the whole medical profession goes out in her sorrow.

The funeral service was held on Wednesday, February 25th, in the little chapel of Gonville and Caius College, where William Harvey worshipped and John Caius lies buried. At the same time a memorial service was held in Great St. Mary's Church. The coffin was carried out through the Gate of Honour, and along Senate House Passage and King's Parade to Trumpington Churchyard. At the funeral service the British Medical Association and its *JOURNAL* were represented by three Cambridge medical graduates: the Association by its President, Mr. J. Basil Hall (Pembroke College), and its Treasurer, Mr. N. Bishop Harman (St. John's); the *JOURNAL* by the Assistant Editor, Dr. N. G. Horner (Caius). The *Lancet* was represented by the Editor, Sir Squire Sprigge (Caius). The large congregation in the University Church included many personal friends and Cambridge colleagues, and official representatives sent by learned bodies and public institutions throughout the country.

Sir ARCHIBALD GARROD, K.C.M.G., F.R.S., Regius Professor of Medicine in the University of Oxford, writes:

To medical men of any living generation it will be hard to realize that Sir Clifford Allbutt has passed away. To those of us who are senior members of the profession his name was already well known in our youth, and to the young of to-day he has been a leader, counsellor, and guide. Generations of his pupils will retain grateful memories of his teaching and affection for their teacher. His writings, and especially

the great *System of Medicine*, which he edited, have gained for him thousands of pupils whom he never saw. At a period of life when most men flag, and claim a well earned rest, Allbutt maintained his bodily vigour; and his keen interest in all the subjects which he had made his own was unimpaired. Despite his years he never grew old. He will be remembered by all who knew him as the ideal physician; as an investigator who approached the study of medicine in a truly scientific spirit; as a scholar, learned in the history and literature of our science and art, and of much which lies outside that field. He held that clear diction and literary form were as desirable in the sciences as in the humanities, and practised what he taught. A knightly figure, and a fitting champion of our aims and ideals, he died, as surely he would have wished, in harness.

Sir HUMPHRY ROLLESTON, Bart., K.C.B., President of the Royal College of Physicians of London, writes:

A friend of my father, Sir Clifford Allbutt had for more than thirty years constantly helped me in innumerable ways, and his sudden death is an irreparable and unexpected break in the established order of things. For though he was in his 89th year he was astonishingly young for his length of days, the only real evidence of age being deafness; in his full sympathy with the young and with fresh ideas and in his broad outlook he indeed compared favourably with many a man of half his years. Aristocratic in appearance and courtly in manner—somewhat resembling the great Lord Dufferin—he was the most approachable of men; obviously a great gentleman, he had indeed a genius for friendship, and I do not think he ever spoke ill of anyone, though he shrewdly estimated the points of character. Like Sir Henry Acland, the Regius Professor of Medicine at Oxford, he had a refreshingly wide and original outlook on medicine, and was more concerned with principles than details. Among his many activities reference may be made to two: his general influence on medical education and culture, and the special subjects in which he initiated advances. He was a scholar in the broadest sense, a profound medical historian, an omnivorous reader, and a persistent advocate of the need for a sound general education as the basis of medical training. With a highly critical literary taste, he was as careful in his own writings as he urged others to be in the choice and use of words. But he was far more than a scholar or a learned man, for his combination of wisdom, humanity, and versatility was of a kind that appears to be dying out in a world that has seen many changes in a comparatively short time. His public addresses were on broad lines and fearlessly independent; thus, in the Goulstonian Lectures for 1884 he satirized the vagaries of the contemporary gynaecologist with a masterly touch, and later, in 1920, expressed his stern disapproval of the practice of psycho-analysis; while in the St. Louis address on the historical relations of medicine and surgery (1905) he insisted on the artificiality of the distinction between the surgeon and the physician. Since his address in medicine at the Glasgow meeting of the British Medical Association in 1888 he had urged the recognition of comparative pathology, and it is a happy outcome of his appeals that there is now an institute for this branch of research at Cambridge, and a Section for its study at the Royal Society of Medicine, of which he was appropriately the first President. No one could write more charmingly of others, as is shown to perfection by his introduction to the volumes dedicated to the late Sir William Osler (1919) and to Karl Sudhoff (1924) on their seventieth birthdays.

He rapidly formed a sound judgement on new work, and was ever alert to welcome the germ of a real advance; thus, in his review (*BRITISH MEDICAL JOURNAL*, 1902, ii, 250) of the book on the pulse by the then little known James Mackenzie of Burnley he generously described it as destined to "take a permanent place in the standard records of the subject." It is indeed remarkable how many matters of now common knowledge in medicine he either originated or made more widely known, though in some instances his share therein has from lapse of time been, perhaps naturally, forgotten. For many years he described hyperpiesia—or, as he originally called it, senile plethora (1895)—and while so doing was largely responsible for the

\* A few copies of the engraving by H. Macbeth Raeburn, after Sir William Orpen's portrait, are still obtainable from the Financial Secretary and Business Manager of the British Medical Association.

introduction of the sphygmomanometer into ordinary practice. His advocacy of the aortic origin of angina pectoris dated from 1894, and those who heard him speak after Professor K. F. Wenckebach's lecture on angina pectoris and the possibilities of its surgical relief at the Royal College of Physicians on May 5th, 1924, were impressed with his mental and physical vigour. He was one of the first, if not the first, to describe syphilitic disease of the cerebral arteries (1868); he was the first in this country to record a case of tabetic arthropathy, a year after Charcot's description in 1868, and he early insisted on the effects of strain on the heart and arteries (1870), on the value of morphine in cardiac disease (1869), on the use of the stomach pump, and of the ophthalmoscope in medicine (1871). Together with the late Mr. Pridgin Teale he advocated the operative treatment of tuberculous glands in the neck (1885), and in 1867 he invented the present short form of clinical thermometer.

Such are a few achievements of the professor, the philosopher, and the physician; but greater even than them were the character and personal influence of the man, the like of whom his friends can hardly hope to see again. He died as he would have wished, in the full tide of his activities; he was to have given the Lloyd Roberts Lecture at the Royal Society of Medicine this autumn, and had a new book ready for the press. Our sorrow is for those left behind; for him there is no feeling but of thankfulness that he had lived so fully and so finely right up to the inevitable end.

In response to our request for a few words from a contemporary in Leeds, Dr. J. E. EDDISON (Woodroft, Cuckfield, Sussex), Emeritus Professor of Medicine in the University of Leeds, has written as follows:

Sir Clifford Allbutt's time in Yorkshire was one continuous success from beginning to end. If I may presume to speak for the medical profession in Leeds and Yorkshire, I should say that he was singularly welcome for his knowledge of his work, for his kindness, and for a gracious manner that he retained all his life. His industry was great, and he had the gift of grasping the points of a case that was always a help to the man who called him in. It was a bad day for Leeds when he left us, and I am glad to remember that I did all I could to prevent his departure. If his career at Leeds was (as it was) a great success, his career at Cambridge may be called a triumph. The medical world began to understand how great a physician he was, and he had a wider field in which to show his various accomplishments and his infinite charm of manner. Now and again in recent years he came down into Yorkshire, and I think each visit he paid only increased the regret we all felt that he ever left Leeds.

Professor W. E. DIXON, F.R.S., who was Sir Clifford Allbutt's assessor in the Chair of Physic at Cambridge, has been good enough to send us the following tribute:

Sir Clifford Allbutt at the time of his death was without doubt the most prominent and courtly figure in British medicine. For a third of a century he had been an outstanding personality in Cambridge and one of the most cultured and learned physicians of the times. He leaves behind him a name which passes to history as representative of all that is noble and great in medicine. His charm of manner, kindness of nature, and graciousness of reception immediately impressed itself on all who came in contact with him.

But apart from this great personality, Sir Clifford was a great man. In his earlier and middle life he had been an active investigator, both experimental and clinical, and in his later years his mature judgement, sense of proportion, and unlimited knowledge of literature enabled him to speak authoritatively on many subjects of medicine, but perhaps especially on cardio-vascular diseases. I remember how Wenckebach delivered before the Royal College of Physicians last May, in which the lecturer said: "Here I knew I would meet the best authority on angina pectoris of this time—your highly honoured, even Right Hon. Nestor of teachers of medicine, my faithful friend in sunny and dark years, Sir Clifford Allbutt." I refer to this only as an example

of the standing and authority in which Sir Clifford was held abroad. Experimental evidence has now placed Sir Clifford's theory of angina on a sure basis, and an ever-increasing number of physicians are adopting his views.

Sir Clifford was an omnivorous reader of medicine and science, and was always ready to discuss or criticize any recent hypothesis or view that had been advanced. As a writer he was facile and graceful; he once told me that in all matters of importance he invariably wrote his manuscript three times. The first time the facts were put down crudely, in the second transcript they were put into good English, and in the third the English was given that graceful style which was so characteristic of the master's hand. He advised his students to get their English from Foster or Darwin; Huxley he regarded as too big for them. The kindness of Sir Clifford's nature was well seen at meetings of his M.D. Degree Committee. On these occasions, whoever the referees for the thesis might be, Sir Clifford himself invariably contributed and read two or more typewritten pages giving his own review of the thesis. In these reports always the good in the thesis was brought to the fore, and he was the most lenient of examiners. Nevertheless, when the thesis had been accepted he ruthlessly informed the successful candidates of their weaknesses, absence of controls, and the like, and if the thesis was really good he would return to the man his own private copy with marginal comments. How he found time to peruse the mass of M.B. and M.D. theses, to take an interest in current subjects of the day, and to read the immense mass of literature—German, English, and French—which he did, was a source of wonder to his juniors.

I often discussed health and longevity with Sir Clifford, and he always insisted that the important factors in good health were moderate exercise, teeth and mouth hygiene (I have even heard him say that all of us at 45 would be better without natural teeth), and nose hygiene.

Sir Clifford was, at all events in the last ten or fifteen years of his life, supersensitive to all kinds of drugs: tea, coffee, and tobacco affected his heart, which even dropped beats if he travelled in a smoking compartment, whilst bouillon at night served to keep him awake. Nevertheless, he was not fastidious, he ate freely of almost everything, though sparingly of meat. Only occasionally did he partake of a little wine, though he was an authority on all that pertained to vintage clarets. A few days before his death he laughingly remarked at dinner that that was always expected from the successful Yorkshire practitioner.

Sir Clifford was the happiest of men; he loved his home, his garden, his work, his University, and his surroundings; exceeding great in his praise of merit in his colleagues and juniors, and tolerant to a fault of their weaknesses. It was the delight of his friends and students to spend Sunday afternoons in his house in the cheery and happy company of himself and Lady Allbutt.

To all who knew him Sir Clifford was not only a great man, but also a great friend, and on Cambridge he has made an abiding impression. Never was honour meted out more worthily than to this, the greatest, humblest, and most beloved physician of our time, whose glory is imperishable.

Dr. H. B. BRACKENBURY, Chairman of the Representative Body of the British Medical Association, writes:

Tributes to Sir Clifford Allbutt's personality and work will come from all branches of the profession. Among these there must certainly be some on behalf of general practitioners and, perhaps especially, of insurance practitioners. Sir Clifford's understanding of the difficulties of these practitioners was remarkable. His appreciation of their opportunities and achievements was always ready. He regarded their work as of the highest importance to the profession and to the public, and was genuinely interested in it. He showed this in many ways. During the four years that he was a member of the Insurance Acts Committee he attended the meetings frequently, and unreservedly placed all his great influence at its disposal. On several occasions during those years, and since, he wrote short memorandums for the Committee and accompanied them on deputations to the Ministry of Health when matters of great moment were under discussion, and as lately as in preparing the case for the Court of Inquiry, early in

# OBITUARY.

FEB. 28, 1925]

1924, he came readily to the Committee's assistance. His knowledge, foresight, understanding, and help in this sphere, as in others, will long be gratefully remembered. His mere presence, indeed, was always an encouragement, and general practitioners of all classes throughout the empire hold him, and will hold his memory, in the most affectionate regard.

We are indebted to one who knew Allbutt well for the following tribute:

It was delightful to watch Allbutt's keen interest in new projects for the advancement of science in connexion with medicine, but he always maintained, nevertheless, that inspiration for advance in medicine must be derived from observations made upon patients. One of the greatest pleasures of his last few years was the realization of a hope he had long cherished of seeing a school of animal pathology working in the closest relations with a school of human pathology. He was delighted when Professor Buxton was appointed under a grant from the Ministry of Agriculture to develop a school of animal pathology, and still further delighted when the splendid benefaction of the Rockefeller Trustees rendered it possible to erect a new laboratory in which the two branches of pathology could develop side by side. He was a lover of art and music, and fortunately, though he found it difficult to hear conversation in his later years, he retained his power of hearing music, which gave him much delight. I cannot put into words the admiration and love I have, and always shall have, for Allbutt. He was a truly great man, great not only in intellect, but in his heart. He was a severe critic, but I never heard him speak unkindly of anyone.

## THOMAS LOWE BUNTING, M.D.Ed., Physician in Charge X-Ray Department, Sick Children's Hospital, Newcastle-upon-Tyne.

THE announcement of the sudden death of Dr. Bunting, on February 18th, has been received with deep regret by the medical profession of Newcastle and Tyneside. It was known to his intimate friends that his health had recently given cause for anxiety, owing to attacks of precordial pain, which were believed to be anginal. Some months ago he had taken a rest from his professional duties, but he had returned to work and was quietly carrying on when the blow fell. Dr. Bunting was a distinguished graduate of the University of Edinburgh. He was a gold medalist in 1904. The writer of this note had the opportunity of reading the thesis which won this distinction for Dr. Bunting—it dealt with the structure and function of lymphatic glands—and was much impressed by the originality of the views therein expressed, many of which have since been accepted. Dr. Bunting, over thirty years ago, commenced practice in the Scotswood district of the city, where is housed a large proportion of the better paid artisan classes of Newcastle. There he built up a large general medical practice; his services were much appreciated and he was held in high esteem. Eventually he took up the study of radiology and visited various important centres where x-ray work was being carried on, and he had already achieved considerable success in the practice of it when the war broke out; this gave him the opportunity he required. He was appointed radiologist to the Northumberland War Hospital at Gosforth. Those of us who were his colleagues have cause to remember his patience, his urbanity, and the great assistance he rendered to the visiting staff. Nothing seemed to be a trouble to him if he could be of service in clearing up a doubtful point in diagnosis.

Dr. Bunting was keenly interested in the politico-social movements of the times. A man of rather advanced views, he did not hesitate to express his opinions, but he never unpleasantly enforced these, nor did he disagreeably differ from an opponent. It was this circumstance which made him so beloved by all, and caused him to be chosen as the mouthpiece of the medical profession when disputable matters had to be considered by a joint body of the profession and insurance, health, or education authorities. At committee meetings on national

insurance matters there was no one, quite independently of the subject under discussion and the divergent views expressed, who was more carefully listened to than the subject of this memoir. He had a wonderful grasp of the intricacies of the Act, what it could and what it could not do, and as he invariably spoke from conviction the opinions he expressed carried great weight and were received with respect. He was a great believer in and a defender of the panel system.

On February 21st his body was laid to rest in Old Jesmond Cemetery. The members of the medical profession attended in large numbers; the various organizations with which he was connected were well represented, as well as the public generally. The British Medical Association was represented by Dr. R. A. Bolam. Dr. Bunting passed away at the comparatively early age of 57 years, before he had time to enjoy the fruits of the greater success which we all believed was in store for him. He left a widow, one son, and a daughter, who is in the medical profession.

T. O.

## R. G. ROWS, C.B.E., M.D.Lond., Hon. D.Sc.Manch., Pathologist, Prestwich Mental Hospital.

DR. RICHARD GUNDRY Rows, who died at Prestwich on January 28th, was born at Tresprisson, Cornwall, the son of Mr. R. G. Rows, chairman of the Cornwall Education Committee. He was educated at Queen's College, Taunton, and shortly afterwards entered University College, London, to study medicine. He graduated M.B.Lond. in 1891, in which year he also took the diplomas of M.R.C.S., L.R.C.P.Lond., and became M.D. in 1892. After a short period in general practice at Reading Rows found his true walk in life. He took up the study of mental disorders, and commenced his life's work at the City Asylum, Birmingham, and after eighteen months there he entered the asylum service of Lancashire, where he found the opportunity of developing the advanced ideas which laid the foundation of his reputation.

A colleague (D.O.) writes:

Rows from the beginning, and while he was in charge of a generously equipped laboratory at the Mental Hospital, Lancaster, based his original investigations on the sure foundation of neuro-pathology. His histological work, his technique, his accuracy, and his criticism, made his opinion of the pathological anatomy of all that concerned morbid processes affecting the nervous system well worth having. On this experience he passed on to the study of functional nervous disorders at a time when a new school of psychiatry was in process of being founded in this country, and his opportunity of assisting this school came during the war. He immediately volunteered, and under the auspices of the Red Cross Society and the Board of Control, assumed the directorship of the large hospital for shell-shock cases at Maghull, near Liverpool. His task was by no means a light one. He had difficulties to counter. His outlook, however, was broad, scientific, and vastly sympathetic; but, guided by his training, and his reading, and scientific insight, he made Maghull such a success that ultimately it became a training school for those who afterwards filled posts under the Ministry of Pensions for the treatment of functional nervous diseases. In addition to all this, his administrative capacity was of the highest, and those who were associated with him spoke in the warmest terms of what they had learnt from him. While in charge of Maghull he held the rank of colonel, and received the C.B.E. and the honorary D.Sc. degree from Manchester University. When he left Maghull he was appointed to two hospitals under the Ministry of Pensions, in which he utilized his experience and inspired a great deal of remarkably useful work. In the spring of 1924 he returned to the Lancashire asylum service at the Prestwich Mental Hospital, where he reorganized the pathological laboratory and at the same time completed a comprehensive work on epilepsy. This was only just finished when, unfortunately, he died unexpectedly, leaving a new and important research incomplete. Rows was a great personality in psychiatry. He was valued as much as a

pathologist as a clinician. His contributions on the inflammatory infections of the central nervous system are well known throughout the world. He was Morisonian Lecturer at Edinburgh in 1920, choosing as his subject "Functional mental illnesses." It was characteristic of Rows's broadmindedness that he broke away from the stereotyped classification of mental disorder. He was right in refusing to pigeon-hole his cases, and he treated each individual case on its own merits with a due regard to individual reactivity. His constant argument was that environment was of more importance than the vague theories of heredity advanced up to the present, and he had a special faculty of entering into the mental conflicts so commonly found in the neuroses. Apart from being a student, Rows's love of outdoor games, of music, and of general literature made him a delightful companion. He was a worker, but played with equal zest, a sportsman in every sense of the term, and combined his capabilities with a becoming modesty. His death has left a gap in psychiatry which will not be easily filled.

## The Services.

### INDIAN MEDICAL SERVICES.

#### PAY OF OFFICERS IN MILITARY EMPLOY.

The Secretary of State for India announces that he has sanctioned the extension to Indian Medical Service officers in military employ of the concessions regarding overseas pay recently introduced for officers of the Indian Medical Service in civil employ and detailed in Statutory Rules and Orders No. 1,395 of 1924, copies of which are obtainable from His Majesty's Stationery Office. The extension has effect from April 1st, 1924. Officers now in the United Kingdom who have been in receipt of rupee rates of pay for any period after this date, and who accordingly have claims for retrospective adjustment under this concession, should address the Controller of Military Accounts by whom they were last paid in India. Indian Medical Service officers in military employ are not eligible for the passage concessions recently introduced for those in civil employ, but will be included in concessions which are being announced separately for the Indian military services.

#### PASSAGE FOR OFFICERS OF THE INDIAN MILITARY SERVICES.

The Secretary of State for India announces that passage concessions as previously foreshadowed have been sanctioned for officers of the Indian military services. They will apply to any passage beginning on or after February 14th. Detailed rules have yet to be drawn up, but the provisional arrangements, which have been approved, are being communicated by the India Office to all officers concerned who are now under the orders of the India Office.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

AN examination for the Theodore Williams scholarship, value £100 a year, and tenable for four or five years, will begin on June 9th. Full particulars can be obtained on application, before May 9th, to the Senior Tutor, Pembroke College, Oxford.

### UNIVERSITY OF LONDON.

#### ELECTION TO SENATE.

THERE are two candidates for election to the Senate to represent the Faculty of Medicine: Sir Holburt Waring, M.B., B.S., F.R.C.S., surgeon to St. Bartholomew's Hospital, the sitting member, who was until recently Vice-Chancellor; and Sir G. Lenthal Cheate, K.C.B., F.R.C.S., surgeon to King's College Hospital. Sir Holburt Waring is understood to be in favour of the Haldane report; Sir Lenthal Cheate pledges himself to "oppose the Haldane recommendations root and branch, and to support the authority of the medical faculty on every occasion."

#### ST. THOMAS'S HOSPITAL MEDICAL SCHOOL.

**Puerperal Sepsis.**—A course of four lectures on puerperal sepsis will be given at St. Thomas's Hospital Medical School by Professor B. P. Watson, M.D., F.R.C.S. (Professor of Midwifery and Diseases of Women in the University of Edinburgh), at 5 p.m. on March 2nd, 3rd, 4th, and 5th. At the first lecture the chair will be taken by Dr. H. Russell Andrews, senior obstetric physician to the London Hospital. Admission to these lectures will be free.

#### UNIVERSITY COLLEGE.

**Vital Statistics.**—A course of two lectures on vital statistics will be given at University College by Professor Harald Westergaard (late Professor of Political Economy in the University of Copenhagen) at 5.30 p.m. on March 9th and 11th. The lectures will be delivered in English. Admission will be free.

**Primary Fellowship Examination.**—A special course for the Primary Fellowship of the Royal College of Surgeons of England, in preparation for the June examination, will begin at University College on Monday, March 2nd.

### UNIVERSITY OF BRISTOL.

THE following candidates have been approved at the examination indicated:

**FINAL M.B., Ch.** . . . . . Crellin, \*† Constance I. Hall, \*† A. I. Alford, A. S. K. F. Platt, I. Terrell, Maria M. Tewater. In E. R. Clutterbuck. In Surgery (completing examination): A. H. Marshall, Dixon. In Public Health (completing examination): Elizabeth E. Denoon, (In Group I only (Surgery and Obstetrics): Margaret P. Posthumus, H. J. Entchwell, Kathleen M. Whitmore. In Group II only (Pathology, Medicine, and Public Health): C. F. R. Killick. PART I (including Forensic Medicine and Toxicology): G. W. R. Bishop, J. F. O. Bodman, Muriel E. Drew, F. S. Dymond, G. L. Foneley, F. R. Gedye, A. P. Gorham, Mildred B. Harver, T. P. Lalonde, M. E. J. Packer, C. B. Perry, L. B. Phillips, E. S. Rogers, A. A. B. Vincent. D.P.H.—V. Ryan. In Part II (completing examination): J. Ledingham. In Part I only: Nora A. McD. Rodger, W. W. S. Sharpe. \* With second-class honours. † Distinction in medicine. ‡ Distinction in surgery. § Distinction in obstetrics. ¶ Distinction in pathology.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN ordinary council meeting was held on February 12th, when the President, Sir John Bland-Sutton, was in the chair.

#### Diplomas.

Diplomas of Membership were granted to 208 candidates. Diplomas in Ophthalmic Medicine and Surgery were granted jointly with the Royal College of Physicians to nine candidates. (The names were printed in the report of the committee of the Royal College of Physicians of London, published in our issue of February 7th, p. 289.)

Diplomas of Fellowship were granted to two candidates (Frederick H. Scotson and Clement Sturton), who, having previously passed the examination, had now attained the age of 25 years.

#### Court of Examiners.

Mr. A. P. Dodds-Parker, surgeon to Radcliffe Infirmary, Oxford, was elected a member of the Court of Examiners in Surgery in the vacancy caused by the retirement of Mr. John Murray.

#### Lecturers.

Mr. James Sberren was appointed Bradshaw Lecturer and Professor Wright was appointed Thomas Vicary Lecturer for the ensuing year. The subject of the Thomas Vicary lecture will be "The mediæval conception of the anatomy and physiology of the central nervous system."

#### Note of Thanks.

The best thanks of the Council were given to Mr. H. R. Hope-Pinker for his gift of a plaster model of his bust of the late Sir George M. Humphry.

#### Council Election.

A meeting of the Fellows will be held at the College on Thursday, July 2nd, at 2.30 p.m., for the election of three Fellows into the Council in the vacancies caused by the retirement in rotation of Mr. V. Warren Low, Mr. James Sherree, and Sir John Lynn-Thomas. Notice of the meeting will be given to the Fellows by advertisement and by circular on March 6th. March 16th will be the last day for the nomination of candidates, and a voting paper will be sent to every Fellow whose address is registered at the College on March 31st.

### SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

**SURGERY.**—J. H. Clapp, J. L. Hopkins, O. W. Percival, C. C. Po, J. Shutt, R. F. Stubbs, B. Temple-Raston. **MEDICINE.**—K. V. Mead, C. C. Po, P. B. Skeels, B. L. Steele, R. F. Stubbs. **FORENSIC MEDICINE.**—A. Henson, K. V. Mead, T. K. Natesan, R. F. Stubbs. **MIDWIFERY.**—N. E. Challenger, T. K. Natesan, O. W. Percival, C. C. Po, J. Shutt, B. Temple-Raston, I. Waynik, G. H. Weber.

## Medico-Legal.

### ILLEGAL PRACTICE BY A DRUGGIST.

A CASE was recently heard in the Nuneaton County Court, before Judge Staveley Hill, in which the Society of Apothecaries of London were plaintiffs and Mrs. Ashton of the Coton Drug Stores, Nuneaton, was the defendant.

The action was brought under the Apothecaries Act, 1815, to recover a penalty of £20 from the defendant for having acted as an apothecary without qualification. From the evidence it appeared that the defendant had treated a child for a cold who was suffering from small-pox, and that as the result of the failure of the defendant to diagnose the disease correctly other people had been infected. The Judge said that, having carefully considered the authorities, he was of opinion that the defendant had brought herself within the statute, and gave judgement in favour of the plaintiffs for the penalty and costs. A stay of execution was granted for fourteen days.

## Medical News.

THE programme has now been issued for the fifth International Congress of the History of Medicine to be held at Geneva from July 20th to 25th, as announced in our issue of October 11th, 1924. On the first day, after addresses by the president of the congress, the president of the Medical Society of Geneva, and others, M. Eugène Pittard, of the Geneva University, will open a discussion on prehistoric medicine with an illustrated lecture on operations in the Stone Age. In the evening a reception will be held by the president of the congress, Dr. C. G. Cumston. Other subjects to be considered include "Albert von Haller and the *disputationes chirurgicae selectae*," by Sir D'Arcy Power; "Robert Whytt, an eighteenth century neurologist," by Dr. J. D. Comrie; the history of typhoid fever in the child, by Professor P. Gautier; a letter of Tronchin and the Suttouian method of inoculation, by Dr. J. G. de Lint; "Voltaire and medicine," by Dr. J. D. Rolleston; "Goitre and Geneva in the Middle Ages," by Dr. E. Wickersheimer; "Lavater and his successors," by M. Fosseyeux; a note on the history of diagnosis in medicine, by Dr. F. G. Crookshank; a letter of Girolamo Fracastoro on poetry, by Dr. J. W. S. Johnson of Copenhagen; historical researches in the history of anatomy in the Ateneo Romano, by Dr. P. Capparoni; medical literature of the seventeenth century, as exemplified in the Elzevir Press, by Dr. E. B. Krumhaar; hygiene and public health in the early civilizations, by Mr. C. J. S. Thompson; the origin of veterinary art, by Sir Frederick Smith; the history of magic in the cure of disease, by Professor Jeanselme; Martin Luther and his noises in the ear, by Professor G. Bilancioni; a medical congress at Rome in 1681-2, by Dr. C. G. Cumston; and Benjamin Waterhouse, an American pioneer, by Dr. J. W. Courtney. On July 23rd an excursion will be made round the lake, visiting the Château of Chillon and the baths of Evian. The subscription, including the cost of excursions and a dinner on July 24th, is 45 Swiss francs. Further information can be obtained from the general secretary, Dr. A. de Peyer, Rue Général Dufour, Geneva.

THE National Union of Scientific Workers informs us that the decision of the Treasury to provide in the estimates for 1925-6 an increase in the grant to the Royal Society towards the cost of scientific publications from £1,000 to £2,500 was due to its representations. It is not intended that the Royal Society should spend the grant on its own publications, but that it should administer it for the benefit of such societies as the Biochemical, the Chemical, and the Physical. It is hard put to it to find money for reports the results of researches in the union, which was started in 1918 to watch the economic interests of scientific men, has its offices at 25, Victoria Street, S.W.1. Its position with regard to the scientific professions is described as corresponding with that of the British Medical Association towards the medical profession. In its relations with Government departments its claim that scientific men should be placed on the same footing as members of the other professions has been largely successful. A similar campaign is being conducted to convince the large industrialists of the benefits to industry arising from the employment of scientific workers.

THE Fellowship of Medicine announces that Sir Arnhthnot Lane will preside at a discussion on post-graduate teaching in London to be held at No. 1, Wimpole Street, on March 18th, at 6 p.m., and open to all members of the medical profession in London. On March 2nd, at 5.30 p.m., Professor H. Maclean will give a lecture on renal disease, its diagnosis and treatment, at the Royal Society of Medicine. A three weeks' course in medicine, surgery, and gynaecology will begin at the Royal Waterloo Hospital on March 2nd, with special reference to gynaecological diagnosis, hernia, diseases of the stomach, intestines, etc. From March 4th to 28th Dr. Frederic Thomson will give a series of demonstrations on the diagnosis and treatment of the acute infectious diseases at the North-Eastern Fever Hospital on Wednesdays and Saturdays at 11 a.m. The Central London Ophthalmic Hospital has arranged an afternoon course in ophthalmology from March 9th to April 4th; for those desiring operative work a class can be held at the Chelsea Hospital for Diseases of the Eye and at the Brompton Hospital for Diseases of the Chest. There will be a fortnight's course to include artificial pneumothorax, bronchitis, demonstrations of cases, x-ray work, protein tests, and the varying phases of chest affections. The Royal Northern Hospital, in conjunction with the Royal Chest Hospital, will hold an intensive course in medicine, surgery, and the special departments from March 15th to April 4th. Copies of the syllabus of these courses may be obtained from the secretary to the Fellowship, No. 1, Wimpole Street, W.1.

SIR W. I. DE COURCY WHEELER (Dublin) completed on February 19th a course of four advanced lectures in surgery at St. Bartholomew's Hospital. The subject chosen was "Fractures of the pelvis and lower extremity treated by conservative methods." The lectures, delivered under the auspices of the University of London, were illustrated by numerous lantern slides.

At the meeting of the Medical Officers of Schools Association on Friday, March 6th, at 4.30 p.m., at 11, Chandos Street, Cavendish Square, a discussion will be opened by Dr. E. W. Goodall and Dr. G. E. Friend on the differential diagnosis of scarlet fever, rubella, measles, and allied rashes.

A MEETING of the Röntgen Society will be held at the British Institute of Radiology, Welbeck Street, London, W.1, on Tuesday, March 3rd, at 8.15 p.m., when a paper on the photometry of fluorescent screens will be read by Leonard A. Levy, D.Sc., and D. W. West, A.I.C.

A MEETING of the Royal Sanitary Institute will be held at the Town Hall, Halifax, on Friday, March 6th, at 4 p.m., with Professor A. Bostock Hill, M.D., in the chair. Two discussions will take place, one on the working of the Milk and Dairies (Amendment) Act, 1922, which will be opened by Mr. John Pollard, M.R.C.V.S., veterinary inspector, and the other on some food dangers, by Mr. H. T. Lea, M.Sc., borough analyst. On the morning of Saturday, March 7th, visits will be paid to certain manufactories and in the afternoon to the corporation salvage plant for domestic refuse and the Bermerside Open-air School and Home.

On the recommendation of the Society of Medical Officers of Health, the Ministry of Health has nominated Dr. James Fenton, M.O.H. Kensington, and Dr. Alfred Greenwood, M.O.H. Kent, for the interchange of health officers to Yugoslavia during May and June next under the auspices of the Health Section of the League of Nations. For the interchange in Belgium about the same time the Society recommended Dr. R. J. Maule Horne, M.O.H. Poole, who has been duly nominated by the Ministry. On the recommendation of the Chief Medical Officer of the Ministry of Home Affairs of Northern Ireland, the Ministry of Health has nominated Dr. Norman C. Patrick also for the Belgian interchange.

SIR AUCLAND GEDDES, President of the Society for the Prevention of Venereal Disease, will head a joint deputation of the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease which the Minister of Health has consented to receive on March 3rd. The object of the deputation is to urge the Minister of Health to give effect to the recommendation of Lord Trevethin's Committee "that the law should be altered so as to permit properly qualified chemists to sell *ad hoc* disinfectants provided such disinfectants are sold in a form approved and with instructions for use approved by some competent authority."

A PORTRAIT of Dr. Isabella M. Macdonald, painted by George Harcourt, A.R.A., has been presented by her friends and patients to the Elizabeth Garrett Anderson Hospital as a memorial of her work there for several years as senior physician.

DR. P. MAUCLAIRE, surgeon to the Hôpital de la Pitié, Paris, has been elected a member of the Académie de Médecine and Professor Barthe of Bordeaux a corresponding member.

THE second Franco-Polish Medical Congress, due to the initiative of the Franco-Polish Medical Society of Warsaw and the Franco-Polish Medical Committee of Paris, will be held in Paris, under the presidency of Professor Roger, dean of the medical faculty, next April, and will be followed by visits to Lyons, Vichy, Strasbourg, and Nancy. Further information can be obtained from the general secretary, Dr. Hinfagel, 10, Rue Freycinet, Paris XVI.

THE fifth international congress for the protection of Infancy will be held at Madrid from April 12th to 20th, under the presidency of Professor Martinez Vargas, rector of the University of Barcelona, who is also president of the International Union for the Protection of Infancy. Further information can be obtained from Dr. Bardclae de Pariente, 10, Square Mouëzy, Paris.

THE fifth Salon des Médecins will be held from March 8th to 20th, at 117, Boulevard St. Germain, Paris, for the exhibition of paintings, sculpture, engravings, and sketches by medical men, veterinary surgeons, pharmacists, and members of their families. Further information can be obtained from the Secretary, Dr. Paul Rabier, 84, Rue Leconrbo, Paris XV.

THE fall in the number of medical students in Germany is shown by the following figures given in the *Deutsche medizinische Wochenschrift*. In the winter term 1922-3 there was a total of 13,489 students, of whom 1,736 were women, and 2,204 foreigners, of whom 336 were women; while in the summer term of 1924 there was a total of only 9,316 students, of whom 1,373 were women, and 1,962 foreigners, of whom 280 were women.

THE West African Medical Staff List, revised up to the end of January, 1925, may be obtained from the Crown Agents for the Colonies, 4, Millbank, S.W.1. Three lists are provided, officers being classed in grades, according to colonies, and according to their qualifications and services.

MESSRS. W. HEFFER AND SONS, publishers and booksellers of Cambridge, have issued a catalogue of new and recent scientific books published by them, or of which they have copies for sale. It is arranged under suitable headings, ranging from mathematics and physics to physiology, anatomy, and medicine. It also contains a list of portraits of men of science the firm has for disposal, and a list of complete sets of journals which can be obtained from them. Copies of the catalogue can, we presume, be obtained from them at 4, Petty Cury, Cambridge.

On his retirement from the post of medical officer of health for Hornsey to take up a similar appointment at Plymouth, Dr. A. T. Nankivell has been presented with an inscribed silver cigarette box by the Mothers' and Fathers' Committee of the Hornsey Maternity and Child Welfare Centre.

In consequence of the outbreak of plague in the Sitapur district, the Government of India has instructed the railway authorities to cancel special trains in connexion with the religious fairs at Nunsar and Misrikh.

## Letters, Notes, and Answers.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Financial Secretary and Business Manager, 429, Strand, W.C.2, on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—not necessarily for publication.

ALL communications with reference to advertisements as well as orders for copies of the JOURNAL should be addressed to the Financial Secretary and Business Manager, 429, Strand, London, W.C.2. Attention to this request will avoid delay. Communications with references to editorial business should be addressed to the Editor, BRITISH MEDICAL JOURNAL, 429, Strand, W.C.2.

Communications intended for the current issue should be posted so as to arrive by the first post on Monday or at latest be received not later than Tuesday morning.

The telephone number of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is Gerrard 2630 (Internal Exchange). The telegraphic addresses are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Antiology Westrand, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westrand, London.

MEDICAL SECRETARY, Mediscera Westrand, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

## QUERIES AND ANSWERS.

### SNOING.

DR. C. W. M. CAMERON (Grantbam) writes in reply to "Wiltshire": In late adult life the muscles which keep the mouth closed tend to relax in sleep more than they do in earlier life and allow the jaw to drop, with the result that the person breathes mainly through the mouth. This causes the soft palate to sag, which produces the snoring noise. I think if "Wiltshire" were to use an elastic chin-strap at night for his patient he would get a satisfactory result.

### INCOME TAX.

"G. R. H." inquires as to the calculation of the amount of profits made on letting a house furnished.

The following expenses are deductible: rent, rates, repairs, agents' fees, and a reasonable amount for use of furniture, say 5 per cent. per annum on the insured value. If the house is owned by the person letting, then in lieu of rent the amount assessed to income tax, Schedule A, is deductible. In addition to the above, any wages paid for gardener and so on would be deductible. With regard to any articles for daily use specially purchased for the use of the tenants and likely to wear out during the period of letting, we think that the inspector of taxes may object that any such allowance would be covered by the general wear and tear allowance based on the insured value of the contents of the house. It may be worth while to claim the deduction, but whether the claim can be successfully pressed depends on the whole of the facts.

## LETTERS, NOTES, ETC.

### CENTRAL MIDWIVES BOARD.

THE Secretary of the Central Midwives Board for England and Wales writes with reference to the paragraph in our issue of February 14th (p. 329) to say that out of nine bodies which send up representatives to the Board, representatives from only three have been reappointed up to the present.

### PLEASANTRIES AT BATH.

IN view of the Annual Meeting of the Association being held this year in Bath, the following verses, from *Eccentric and Humorous Letters*, an olla podrida concocted in 1824, may interest and perhaps amuse.

At the time that Dr. Cheyne and Dr. Winter were the two principal physicians at Bath, they adopted very opposite modes of practice; but the former gained some credence for his prescription of milk diet by making it the principal article of his own maintenance. On this occasion Winter wrote him the following stanzas:

#### To Dr. Cheyne.

Tell me by whom, fat-liver'd Scot,  
Thou didst thy system learn;  
From Hippocrate thou hast it not,  
Nor Celsus, nor Pitcairn.

'Suppose we own that milk is good,  
And say the same of grass;  
The one for babes and calves as food,  
The other for an ass.

Doctor, no new prescription try;  
A friend's advice forgive:—  
Eat grass, reduce thyself, and die,  
Thy patients then may live.

To this effusion Dr. Cheyne replied as follows:

My system, Doctor, is my own.

No tutor I pretend;

My blunders hurt myself alone,  
But yours your dearest friend.

Were you to milk and straw confined,  
Thrice happy might you be;  
Perhaps you might regain your mind,  
And from your wit get free.

I can't your kind prescription try,  
But heartily forgive;

'Tis not I, but you should bid me die,  
That you yourself may live.

Dr. George Cheyne, the target of Dr. Winter's shafts of wit, was a native of Aberdeenshire, and was born in 1671. He was at first intended for the ministry; his leaving, however, was towards medicine, and he was persuaded to adopt that profession by Dr. Pitcairn, under whom he studied. Having obtained the degree of M.D., he commenced practice in London, though without belonging to the College of Physicians. On coming to London he suddenly changed his former temperate, sedentary habits, and frequented the society of "the younger gentry and free livers," with whom he became extremely popular, for he had a genial temper and a ready wit. This life was greatly to his liking—it was not only pleasant but was of use in bringing him professional business; it, however, aggravated a natural tendency to corpulence, which, with other troubles, caused him much distress. He therefore abandoned his free habits of living and adopted a rigorous moderation, which brought some alleviation but cost him the loss of his pleasant companions and a good deal of his professional work. His health was eventually fully restored after a course of the Bath waters. Some time later he relinquished his abstemious for a "moderate" diet, and his old enemy, corpulence, so gained upon him that he eventually attained the enormous weight of 32 st. and was hardly able to walk. To reduce his weight he adopted for the remainder of his life a milk and vegetable diet; it is to be gathered, too, that he recommended this regimen to his patients, which seems so to have roused Dr. Winter's ire that he penned the gibe printed above.

Dr. Cheyne was a voluminous writer, though few of his works were purely medical. It was one of his earliest works, *Fluxionum Methodus Inversa*, one authority asserts, that procured his admission to the Royal Society.

### CORRECTION.

DR. R. H. COLE asks us to correct two errors which appeared in the summary of his address, delivered before the Kensington Division, on "The present legal disabilities in the early treatment of mental disorders," published last week at page 357. In column 1, line 15 from foot, for "1884-5" read "1844-5." In column 1 of page 358, line 22 from top, for "and rate-supported hospitals" read "but not over rate-supported hospitals." The Board of Control has no power over rate-supported mental hospitals.

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 44, 45, 48, and 49 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 53.

## An Address

ON

## ENCEPHALITIS LETHARGICA.

GIVEN TO THE SOUTH MIDLAND BRANCH OF THE BRITISH MEDICAL ASSOCIATION

BY

C. M. HINDS HOWELL, M.D., F.R.C.P.,

ASSISTANT PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL, LONDON.

In the spring of 1918 a series of cases appeared in this country which presented certain novel features. Professor Arthur Hall and Dr. Wilfred Harris independently drew attention to this occurrence in adults, whilst the late Dr. F. E. Batten published an account, under the title of "Epidemic stupor in children," of a series of cases which had been under his observation at the Hospital for Sick Children, Great Ormond Street, London. The suggestion was made tentatively that the cases might possibly be examples of botulism, with which they had some features in common—namely, ocular palsies, drowsiness, muscular weakness, and sphincter troubles. The food supplies at that time were not of the best, but it soon became obvious that the cases, which were appearing in increasing numbers, had nothing to do with *B. botulinus*, but were evidence of a widespread epidemic. Attention had already been called to its occurrence in 1917 by von Economo in Austria and by Netter in Paris.

Since that date we have had the disease constantly with us. In January, 1919, notification was made compulsory by the Local Government Board. The number of cases notified since then has been: 541 in 1919, 890 in 1920, 1,470 in 1921, 454 in 1922, and 1,123 in 1923. So far as I can judge, the figures for 1924 are likely to be as high as those for 1923, or even higher. It is, of course, probable that all cases of the disease are not notified, as many atypical cases occur in which the diagnosis is likely to be missed.

## ETIOLOGY.

Certain facts have been brought out as the result of notification. The incidence of the disease is highest in the winter months January, February, and March; in this respect it offers a striking contrast with the seasonal incidence of poliomyelitis—a matter of some importance when considering the etiological relationship of these two diseases.

The age incidence is fairly evenly distributed. The disease may occur in babies or septuagenarians. In this respect also it offers a striking contrast with poliomyelitis, as in the latter 80 per cent. of the cases occur under the age of 20. The disease is contagious to only a very slight degree; in my own experience I have not come across more than one case in any one family, nor have I any experience of infection occurring in hospital, either among patients or nurses, in a ward in which cases of encephalitis were being cared for. In this respect the disease resembles poliomyelitis and meningococcal meningitis. But cases are on record of direct spread by contagion, though their numbers are few. In 1919 I had under my care a woman with a typical attack of encephalitis lethargica who was nursing a baby a few weeks old, and who had done so for at least a fortnight. The mother's attack was very severe, but the baby escaped infection. Hall, in his monograph, quotes a similar case in which the child became infected and died, and another which shows perhaps that there is a possibility of infection being carried through the mother's milk. In this case a pregnant woman developed the disease two weeks before her child was born. The child was at birth quite healthy, lively, and active. After being put to the breast it gradually developed torpor and somnolence. It was weaned, and almost immediately recovered and remained well.

The actual infecting organism has not been satisfactorily identified. From von Economo's cases von Weisner recovered a streptococcus growing in pairs, and in one of two monkeys he reproduced certain symptoms of the disease—lethargy, dysphagia, and paralysis—but subsequent investigations have failed to confirm these findings.

In 1919 and 1920 Strauss, Hirschfeld, and Loewe succeeded in reproducing the disease in a monkey (*Macacus rhesus*),

and in rabbits, by using emulsion of brain from cases of encephalitis lethargica. They were also successful with washings from the nasopharynx of living patients. They isolated a virus from this material which proved to be a filter-passer, and also to be capable of preservation in glycerin. In these respects it closely resembles the virus of poliomyelitis.

It is probable that in both these diseases, as also in meningococcal meningitis, the infecting agent gains access to the central nervous system through the nasal mucosa, and that in all of them "carriers" exist. The separation of a virus from cases of herpes labialis, which experimentally reproduces many of the symptoms of encephalitis lethargica, is a matter of great interest, but does not lessen—indeed, it rather increases—the difficulties. This virus also is a filter-passer and can be preserved in glycerin.

Levaditi and his co-workers conclude that encephalitis lethargica is due to a specific virus with the characteristics already referred to, and that it exists in an attenuated form in the saliva of healthy persons, in a more virulent form in the vesicles of herpes labialis, and in its most virulent form in the saliva of carriers, and in the nasopharyngeal mucosa and nervous tissues of persons suffering with encephalitis. These results have not been universally confirmed; Flexner and others having failed to get any positive results with inoculations from cases of encephalitis.

At this point I want to say a few words about the possible relationship of encephalitis lethargica to influenza.

Experience of the last few years has shown that outbreaks of the two diseases are apt to occur simultaneously. Further, a review of past influenza epidemics reveals the fact that cases presenting a clinical picture very similar to that of encephalitis lethargica occurred at these times. It seems clearly established that epidemiologically there is a close connexion between influenza and a group of diseases affecting the nervous system, of which encephalitis lethargica, cerebro-spinal fever, and poliomyelitis are members. The suggestion was made in the early days of the encephalitis epidemic that it might be a cerebral form of influenza. If such were the case we should expect to find cases of encephalitis lethargica and influenza occurring in the same household, as no disease is more highly contagious than the latter. This relationship, however, is far from existing. Moreover, we have seen that encephalitis lethargica appears only exceptionally to be contagious to any marked degree. We must leave it to the future to determine to what extent these diseases are mutually related.

Epidemic hiccup has occurred in various outbreaks since the appearance of encephalitis lethargica, and the question has arisen whether it may not be a manifestation of the latter disease. There is no positive evidence that it is, and some evidence to show that it is not; persistent hiccup is not a common symptom in definite cases of encephalitis lethargica, and cases of hiccup do not as a rule exhibit other symptoms suggestive of encephalitis. Recently, however, I had under my care a medical man with epidemic hiccup, who also had definite evidence of an encephalitis, as the result of which he developed hemianopia. Epidemic hiccup would appear to be more definitely contagious than is encephalitis lethargica.

## SYMPTOMS.

We are dealing with an infection which produces tissue reactions scattered at random throughout the whole nervous system; the main incidence is now in one place, now in another. The clinical picture will be determined by the extent of the damage done to the several parts of the nervous system involved. Meninges, cortex, centrum ovale, basal ganglia, mid-brain, pons, medulla, spinal cord, and even at times peripheral nerves, may each and all of them become involved. It is true that the chief focus of the disease is apt to be in certain localities more than others, the mid-brain and basal ganglia perhaps especially; the result is that what has been described as the oculo-lethargic type recalls the clinical picture that we all should regard as probably most characteristic of the disease. It is indeed a picture which is rarely produced by other conditions, and in its most typical form by none. To multiply types of this disease by naming some dozen or more syndromes by their most striking features serves no useful purpose.

The onset of the disease may be acute and dramatic in the suddenness and severity of the symptoms produced, or it may be very insidious. In my experience the oculo-lethargic group of cases are likely to belong to the latter category. I have seen a number of such cases, referred to me on account of a diplopia of doubtful origin, and complaining of little else. The initial period in these insidious cases may be prolonged, constituting what may be regarded as a prodromal period in which the chief symptoms are lassitude, somnolence, slight headache, depression, and irritability. When the disease enters on a more active stage, and in cases of sudden and acute onset, fever is, I think, always present. Its duration may be a matter of hours, or it may be present for weeks, but the febrile period is as a rule short: I have had two cases under my care in which the patient was febrile for a period of eight weeks. One of these patients recovered. Cases in which the febrile period has lasted for months are on record, but these are fortunately quite exceptional. Although commonly of low grade, high degrees of fever, sometimes even hyperpyrexia, may occur. The latter is usually, but not always, a terminal event. A steadily rising temperature at the end of a prolonged period of pyrexia is an ominous sign. The tongue is heavily furred, often greenish or brownish-white, the breath foul, and the bowels usually severely constipated. Abdominal pain, associated sometimes with vomiting, may occur. I have recently seen a case which was admitted to hospital as appendicitis.

There is nothing remarkable in the condition of the pulse, nor in the lungs, but there may be peculiarities in respiratory rhythm during the active stage of the disease. Polypnoea with periods of apnoea has been observed on several occasions, due almost certainly to disturbance in connexion with the respiratory centre in the medulla. Drowsiness is one of the striking features of the disease, both in its active stage and as a sequel. It is often one of the earliest symptoms.

I saw in May, 1924, a man of 60, who gave the following history. He had started the year with an attack of influenza, which left him with sciatic pain, for which he took salt baths at Southend. In the middle of April he had his usual bath and then sat down on a seat on the parade. Here he found that he had diplopia, felt sleepy, and complained of slight headache. He travelled to London, arriving about 8.15 p.m. On his way home from the station he went to sleep in the road, lying down against a tree. He was awakened by a policeman, who suggested he should go home to bed, and evidently thought that my patient had been drinking. He started for home, but was overcome with sleep a second time. He reached his home about 4 a.m. Normally he should have got there in fifteen minutes from the station.

Another patient—a man of about 40—was playing in a two-day cricket match. On the evening of the first day he noticed that he heated atmosphere and went home to bed. He put this down to the next day with success, and with no visual troubles. He played cricket all ride home on a motor bicycle about 5 p.m. to go perhaps thirty or forty miles. He has no recollection of anything after that till 4 o'clock the next morning, when he found he had been asleep by the side of the road about a mile from home. He was able to waken his chauffeur, who lived close by, and was assisted home by him.

The condition of drowsiness frequently advances to one of seemingly profound lethargy; it is remarkable how a patient in such a condition can be roused to answer a question intelligently, but at once relapses again. The lethargic periods often show remarkable remissions. A boy under my care would be profoundly lethargic during the morning, going to sleep whilst the nurse was endeavouring to give him food, but in the afternoon would become quite wide awake and alert, and demand comic papers.

With this pronounced lethargy the patient may frequently suffer from insomnia. This may simply be inability to sleep at night, but is sometimes accompanied by nocturnal excitement. A girl in St. Bartholomew's Hospital was profoundly lethargic by day, but at night became extremely excited, sang songs at the top of her voice, wanted to jump out of bed, and threw anything left within her reach at any nurse who happened to be near. Mental symptoms are frequently observed: the mildest is a lack of restraint comparable in many respects to the mental condition of one not drunk, but "having drink taken." A young man recently under my care suffering from diplopia, slight fever, and a moderate degree of drowsiness, insisted on explaining at great length how badly he had treated a girl to whom he had been engaged, by breaking off the engagement in a most incon-

siderate manner. In his normal mental condition he is a very reserved personality. Delirium of a "busy" kind is common. I have heard patients carrying on imaginary conversations on the telephone, dictating letters, smoking imaginary cigarettes, and so on. Sometimes, though I think only occasionally, a patient becomes maniacal.

One very striking case of the kind occurred in a patient under my care in 1918. He remained more or less comatose for about six weeks, and then became maniacal. Arrangements had just been completed for his removal to more suitable surroundings when the attack of mania ended as suddenly as it had begun, and he became quite normal, all trace of lethargy passing away at the same time as the mania.

Among symptoms due to lesions in the nervous system ocular phenomena take first place. Any or all of the oculomotor nerves may be involved, the paralysis usually being of the nuclear type with conjugate movements affected. Ptosis is extremely common, and helps to add to the appearance of somnolence which is so characteristic. The pupils show a variety of changes—small, dilated, unequal, the Argyll Robertson type, failure to react to light or accommodation. Much interest attaches to the condition of the optic disc. Papilloedema, which at one time was thought never to occur, is now recognized as being present occasionally; usually it is of low grade with but little swelling; haemorrhages are rarely met with. An intense papilloedema with much swelling and haemorrhage makes the diagnosis of encephalitis lethargica extremely doubtful.

I recently saw a patient who was suffering from intense headache, was drowsy at times, had a nuclear paralysis of the third nerves with loss of upward movement of the eyes. All this was sudden in its onset and the patient was thought to be suffering from encephalitis lethargica. Examination of the disc revealed the presence of an intense papilloedema with haemorrhages. A diagnosis of mid-brain tumour was accordingly made, and verified, unfortunately, at a subsequent autopsy.

Other cranial nerves may be affected, the commonest in my experience being the seventh. I have never seen examples of paralysis of the fifth or twelfth nerve, though it has been observed. The patient may quite early exhibit the Parkinson facies, with characteristic attitude of the arms and hands, rigidity, and, less commonly, tremor. Where these symptoms occur early I have thought the prognosis, even as regards life, to be grave and that the Parkinsonian sequel was assured in the event of the patient surviving. This view may, however, prove quite erroneous.

A girl of 17 was admitted under my care at the National Hospital in the early and acute stage of the disease. She had already developed a very severe degree of the Parkinson syndrome—was quite unintelligible in her speech, saliva dribbling from her mouth, and incontinent. I gave an extremely bad prognosis as regards recovery, and said that if she did recover she would be a hopeless case of paralysis agitans. Both predictions happily were entirely wrong. She made a complete and uneventful recovery, and is at present a member of a theatrical company, and very successful, I understand, as a dancer.

Buzzard and Greenfield first drew attention to the occurrence of hemiplegia as a symptom of encephalitis lethargica, and many such cases have since been observed. There is, of course, nothing characteristic in the hemiplegia itself, and often the diagnosis can only be made by a careful consideration of the circumstances in which the condition developed, and by a reasoned process of exclusion. Katatonia has been present in a large number of cases, and when present may be an important aid to diagnosis. Considerable interest also attaches to a number of other motor disorders of an irritative character. Among them must be mentioned fits, choreic movements (of which many cases appear to have occurred in the recent outbreak), a more pronounced type of involuntary movement designated under the title of choreo-athetoid movements, myoclonus, and muscular spasm. Epileptic attacks may occur as an initial symptom, during the course of the disease, or as an after-effect; they are more likely to occur in those cases in which the cortex is most involved, and in such cases present the common picture of clonic convulsions; but in cases where the mid-brain is chiefly involved "tonic fits" may occur, associated with rigidity and extension of the limbs. Fits, however, are not a common symptom in the disease. Involuntary muscular movements are more frequently met with. Two cases were admitted recently to St. Bartholomew's Hospital as chorea, but in the wards the nature of the cases became clear. Cases of choreo-athetosis are much less common. I have seen only one of the kind; it was

treated in the National Hospital. The movements and gesticulations exhibited were of a particularly striking character, though they did not develop until eighteen months after the initial illness.

Myoclonus occurs in a fair number of cases; the muscular contractions may involve the whole or part only of any particular muscle, sometimes causing movement of a limb and sometimes not. The muscular contractions are usually painless, but severe cramp-like pain may be experienced, and this, I think, more particularly when the abdominal muscles are involved. Muscular spasm sometimes persists for a long period, and I have seen one patient with a residual torticollis, which still persists. Peripheral nerve palsies rarely occur. I have seen two or three such cases in which the external popliteal nerve was affected, with resulting foot-drop; and another remarkable case in a boy of generalized weakness with moderate muscular wasting and absence of reflexes which suggested widespread peripheral neuritis.

Pain, apart from muscular spasm, has been noted in a number of cases. I have already referred to the case of a boy who was admitted to hospital with abdominal pain and vomiting as the result of which he had been diagnosed as a case of appendicitis. In other cases the diagnosis of rheumatic fever has been made. I have seen two such cases recently. It is interesting to note that a similar mistake is sometimes made in connexion with poliomyelitis.

#### SEQUELAE.

I must now briefly refer to the sequelae. With regard to these it may at once be said that the diagnosis of encephalitis lethargica is in many cases more easily made in the presence of its consequences than during the initial attack.

One of the most striking sequels is paralysis agitans. I have referred already to the early appearance of Parkinson symptoms; they may entirely disappear, or pass into a chronic and persisting residual condition. On the other hand, cases in which the patient appears to have made a good recovery may begin many months later to develop the characteristic symptoms of paralysis agitans. Its features resemble very closely those of the ordinary senile type—facial immobility, weakness and rigidity of the limbs, the flexed attitude, the gait, are all present. Tremor is the symptom which is most likely to differ, in that it is not, in my experience, either so common, or when present so constant, as in the senile form. It may have a partial distribution, usually hemiplegic. I have several patients who show this well.

Residual ocular paralysis is common—the degree very variable. When all other movements have returned it is not uncommon to find that convergence is still faulty. Mental changes are also unfortunately very common. The bright child becomes dull, the "easy" child "difficult." Depression, sometimes amounting to melancholia, is not uncommon, and easily to be understood, in the cases with the Parkinson syndrome. More than one of my patients has stated, "I have forgotten how to laugh"; in some all emotional response has disappeared.

Impulsive tendencies are noticeable in a few cases; one of my patients always felt the strongest impulse to get in front of express trains, or if water were rushing under a bridge to jump into it, though she had no wish to commit suicide. She presented Parkinson symptoms, and the rapid movement made an almost irresistible appeal to her. A certain number of cases drift into asylums, but fewer than might be expected. Disorders of sleep may persist long after the acute stage of the disease is over—somnolent by day, the patients may awake to an excited activity at night. I do not know the meaning of this inversion, but its presence I have noted many times.

Involuntary movements, spasms, and ties of various kinds are not uncommon; several cases of the latter I have seen in connexion with the respiratory movements. Residual paralysis in the form of monoplegia or hemiplegia is met with in those cases in which it has been present during the initial stages. It does not tend to develop after apparent recovery in the same way as paralysis agitans commonly does. Seborrhoea of the scalp and forehead, sometimes to a most striking degree, may be noted. Lastly, obesity,

possibly as the result of some disordered function of the pituitary, has occurred in a number of cases.

This list does not pretend to be in any way comprehensive, and I have no doubt that other sequelae have been observed. I have stated here those which in my own experience have proved most likely to occur.

I must not leave this aspect of the disease without making some reference to relapse. This occurs in an acute form in a number of cases. It is uncertain at what period we can regard a patient who has suffered from the disease as free from danger of relapse or the development of the dreaded Parkinson syndrome. I have observed what I thought was relapse in a case of this kind exactly two years after the original attack. The very long interval made me somewhat doubtful of the correctness of the original diagnosis, but reports of similar intervals, though unusual, have been made.

#### PATHOLOGY.

Macroscopically there is very little to see in these cases. Occasionally there are meningeal haemorrhages, usually quite small, but sometimes moderately extensive. The meninges may have a milky appearance if the superficial cellular exudate has been considerable. The brain on section is softer than normal, and numerous punctate haemorrhages are visible. These haemorrhagic points are probably the most constant macroscopic finding.

Microscopically the most striking and obvious appearances are furnished by a perivascular collection of small round cells which fill the Virchow-Robin space and form a cuff to the blood vessels. The cells in this exudate are for the most part lymphocytes, but plasma cells are also to be found. The exudate may be seen in connexion with capillaries, veins, and arterioles. The majority of observers regard this as a cellular exudate, though Buzzard and Greenfield are of the opinion that the cells are entering and not leaving the blood vessels.

There is for the most part no cellular reaction in connexion with the vessel wall, but a remarkable occurrence is calcareous arterial degeneration, which has been frequently observed. This is chiefly to be found in the vessels of the anterior part of the globus pallidus of the lentiform nucleus; it is sometimes accompanied by thrombosis of the affected vessel. It is remarkable how early this calcareous degeneration may occur. Far from being a late change in the neighbourhood of an inflammatory focus, calcification has been noted as early as the seventh day of the disease. Collections of cells are also met with, apart from the vessels, in the tissues. The vascular changes and cellular foci here referred to may occur throughout the whole of the nervous system, not excluding the spinal cord. The pains, myoclonus, and muscular spasms that occur as clinical manifestations of the disease no doubt owe their existence to these scattered lesions.

Changes in the nerve cells are met with, similar in character but much less extensive than are found in poliomyelitis. The changes consist of (1) neuronophagia, in which the nerve cell appears to be undergoing a destructive change as the result of the activities of proliferated neuroglial satellite cells; (2) chromatolysis, with swelling of the nerve cell, eccentricity of its nucleus, and diffuse staining of Nissl granules; (3) neuroglial proliferation. In cases of the Parkinsonian type many observers have described profound degenerative changes in the cells of the substantia nigra in the mid-brain. This has opened up a wide field for further investigation which is likely to throw light on the physiological functions of the cells of the substantia nigra. In addition to these changes, fatty globules, which tend to become agglomerated and to undergo calcareous deposition, have been observed in many cases.

Contrary to what might have been expected, the cerebrospinal fluid usually shows few changes from normal. But changes may be met with in connexion with the cells and the protein and sugar content. Although the count of cells is usually lower than 10 cells per cubic millimetre, there may be a considerable increase—counts of 30 to 80 cells per cubic millimetre are met with occasionally. It is very rare to find more than 100 cells, and if such a number are present it suggests meningitis as opposed to encephalitis lethargica. These cells are almost entirely lymphocytes,

in which respect this disease resembles poliomyelitis, and incidentally tuberculous meningitis—a disease which often causes a good deal of difficulty in diagnosis.

The protein content of the cerebro-spinal fluid rarely shows any marked increase, whilst the reverse is the case in meningitis, but 0.03 per cent. is sometimes met with. The chlorides are not altered—another point which in a doubtful case may prove of use in making a diagnosis of encephalitis as against meningitis. In the latter the chlorides constantly show a small reduction. Any figure below 0.68 per cent. would suggest meningitis very strongly. So, too, with the glucose content. In encephalitis this is unaltered, or even slightly increased, whilst in cases of meningitis, and more particularly tuberculous meningitis, the quantity is substantially diminished or absent. Changes in the blood are not striking—a small leucocytosis with a total count of 10,000 to 12,000 may be expected.

#### DIFFERENTIAL DIAGNOSIS.

Encephalitis may be extremely easy or impossible to diagnose. Often it is much easier to recognize from its sequels than during the initial stages. Whilst it is true that in many cases the disease has escaped recognition, it is no doubt also true that in the interest aroused by the advent of a new disorder—at any rate new within our experience—many cases have been labelled encephalitis lethargica which were nothing of the kind. Of acute infections, those most likely to cause trouble in diagnosis are influenza and tuberculous meningitis. The former suggests encephalitis in those cases in which headache, prostration, drowsiness, and fever are the prominent symptoms, whilst the latter may exactly reproduce the clinical picture of encephalitis.

The absence of such signs as retraction of the abdomen, rigidity of the neck, Kernig's sign, and tache cérébrale should help in the diagnosis, though the intrinsic value of each as a diagnostic sign is slight. A careful comparison of the cerebro-spinal fluid in conjunction with the clinical picture should help materially in the recognition of tuberculous meningitis and make the diagnosis certain if other forms of meningeal inflammation are present.

I have already referred to possible difficulties in connexion with chorea, and to errors which occasionally arise in connexion with abdominal pain and rigidity. Vascular lesions may cause great difficulty, and I think that in connexion with these the diagnosis of encephalitis is more likely to be made in error than the converse. The age of the individual is no help in this connexion, as we have seen that encephalitis has no regard to age. Tumour or abscess of the brain sometimes suggests encephalitis, but the presence of papilloedema of a marked type would be much in favour of tumour, although we have seen that a low-grade papilloedema sometimes occurs in encephalitis. The absence of any probable cause for abscess should help in its exclusion, but the presence of an ear discharge, present or recent, does not exclude the possibility of encephalitis.

#### PROGNOSIS.

Even more difficult than diagnosis is prognosis. Two points have to be considered: will the patient recover, and, if so, will recovery be complete? or will one or other of the sequelae arise? The answer to the first question may remain long in doubt. No definite answer can possibly be given to the second.

Severity of onset does not necessarily imply a fatal issue, nor should too optimistic a view be taken with regard to a case of insidious and apparently mild onset. It would be possible to quote many cases to illustrate the truth of this. Cases with a prolonged febrile period are, I am sure, dangerous. I have referred already to the ominous significance of a slowly rising temperature after a febrile period of two or three weeks. Statistics of the mortality of the disease have varied from 30 to 50 per cent.—figures which are, of course, quite useless in helping to make a prognosis in any individual case.

With regard to sequelae, one can say that of the cases which recover perhaps 50 per cent. will have residual symptoms, from some of which, notably the Parkinson syndrome, they may die. Many of these sequelae no doubt will be slight, and not in themselves disabling. It is important to

remember that a case which has made an apparently perfect recovery may develop some sequel at any time in the next two years. After that period I should say the risk was negligible, and the majority of patients show evidence of incomplete recovery within twelve months.

#### TREATMENT.

There is unfortunately no specific treatment that has proved its value. I am convinced of the importance of recognizing the early ambulatory type of the disease and putting the patient to bed. There treatment on general lines must be carried out in so far as diet and regulation of the bowels are concerned. Most of the patients suffer with obstinate constipation.

A gargle of potassium permanganate may well be used by the patient, if he is in a condition to so do—and by those in contact with him.

With regard to any special therapeutic measures, it is safe to say that none has so far offered convincing evidence of success. Hexamine has had an extended trial, by the mouth, hypodermically, and intravenously, but the results have been disappointing. In some cases serum, either from the patient, or simple horse serum, and in some cases anti-meningococcal serum, has been used apparently with advantage. Repeated lumbar puncture has been recommended, although it is difficult to see on what logical grounds; I have, however, seen an improvement in the depth of the lethargy follow a lumbar puncture. Insomnia, delirium, or excitement can be dealt with on ordinary lines. The residual symptoms or sequelae are extraordinarily resistant to every therapeutic measure.

## THE ANTE-NATAL CLINIC.\*

BY

GUY BELLINGHAM SMITH, M.B., F.R.C.S.,  
SENIOR OBSTETRIC SURGEON, GUY'S HOSPITAL.

I HAVE chosen the subject of the ante-natal centre, not because I am the best fitted to deal with it, but as an act of atonement for a certain lack of faith in the first instance. Those of you who, like myself, have worked for years amongst the very poor know how, with their poverty, goes a certain pride, which resents interference in their affairs. I thought of the difficulties we should have in getting the confidence of these people, and I was unable to anticipate the results that have followed the working out of the scheme. I was reckoning without their enthusiasm and tact that sisters and health visitors have brought to the work, and the enthusiasm again and knowledge that those responsible for the medical side have shown.

I am surprised sometimes at reading the statistical results of fifty years ago, and we occasionally come across to-day despondent remarks as to the progress made in midwifery. These are mainly based on mortality results, and more particularly on those relating to puerperal fever. I have no doubts as to the progress made, having watched the results over a period of forty years. To begin with, figures are not always reliable, and we must remember further that the range of work dealt with to-day is enormously greater than it was at that time, and that mortality results are more accurately stated. When we remember that our armamentarium consisted of a bottle of ergot, often administered too soon, and a Higginson-syringe, which was used indiscriminately for the rectum and the uterus, we may wonder that the results were so good as they were.

But, however we may argue about death rates, who can doubt the enormous improvement that has taken place in the morbidity results? Where are the cases of vesico-vaginal fistula that were a commonplace in the operating theatre of a few years past? Where are the sequelae of severe injuries and sloughing of the vaginal passage, the atresias, the entire loss of the urethra or of the posterior bladder wall? I never see them to-day.

During the last year or two there has been a complete revolution in the hospital practice of midwifery. For many

\* The Purvis Oration, delivered before the West Kent Medico-Chirurgical Society, December 12th, 1924.

years after I started work it was a case of "alarums and excursions," almost invariably at night. Nothing was foreseen. Operations were extemporized in the bedrooms of the poor. I do not know that it was, but it ought to have been, one long nervous strain.

Gradually some improvement came when hospital beds were provided for urgent cases, and we managed to get the more severe cases of pelvic deformity to attend earlier for adequate arrangements to be made. This diminished greatly the number of cases in which the cephalotribe was used. To-day one has peace of mind. Nearly everything is foreseen; very little is left to chance. The extern goes to the patient with a complete history of his case. The cephalotribe and the high forceps will soon, I hope, be a matter of past history.

I will describe shortly the working of the Salomon Infant Welfare Centre at Guy's Hospital, the only one of which I have any knowledge.

In 1918 the hospital received from the executors of the late Mr. Leopold Salomon £10,000 to endow an infant welfare centre, and on receipt of this money a committee, composed of representatives of the governors, the hospital staff, and outside persons interested in infant welfare, was appointed, and as a first step took over three houses adjoining the hospital, and by their conversion provided accommodation for ante-natal and post-natal clinics, and for the residence of a sister superintendent, six health visitors, and a domestic staff. The medical staff consists of the two obstetric assistants who are responsible for the ante-natal clinics, and two medical officers who are responsible for the post-natal treatment of the mothers and for the welfare of the children up to the age of 5 years.

I like to mention the names of the two men who during these six years have organized the ante-natal work, who have made this department the success that it undoubtedly is, and who will no doubt bring before you one day something more solid than the scraps I bring with me. They are Mr. McNair and Mr. Cook, and to them I owe a great deal that this paper contains. The area of the ante-natal clinic is that of the old maternity district, which extends about a mile round the hospital.

The procedure is shortly as follows. Pregnant women living in the maternity district apply to the almoner of the hospital for a card entitling them to attendance by the hospital during their confinement. Their circumstances having been inquired into, and it being found that they are eligible for treatment, they are referred to the ante-natal clinic, where they undergo a thorough examination by the medical officers. Attention here is paid not only to the complications directly due to pregnancy, but also very particularly to such conditions as heart trouble, phthisis, the teeth, and the health generally.

Great stress has been laid upon the teeth, the condition of these in poor people leading to much anaemia and debility. In consequence a special dental clinic has been instituted under the care of a special dental officer, to whom expectant mothers are sent to have their teeth seen to. We are satisfied that an enormous improvement in health has resulted, the patients becoming better nourished and better able to nurse the children. The mothers attend at regular intervals, according to instructions, up to the time of the confinement, the number of these visits depending naturally upon the presence of some abnormality relating to the pregnant condition or to the general health. In 1923, 2,210 mothers attended during the year, with a total number of visits of 6,773. It will be seen that this represents a large out-patient department, and that it throws a lot of work on my junior colleagues. Not only are the cases seen here, but they are referred when necessary to the different departments of the hospital for special opinions and advice, some of them being admitted either to the obstetric or to the medical wards.

I referred at the beginning of this paper to difficulties that I anticipated. But I underrated the importance of the hospital connexion. For a long period the district surrounding the hospital has depended on the maternity charity for its confinements, and in this way has grown up a trust in us that was stronger than I realized. It may be some such faith in us that has led to the centre being known in our district as "Salomou's welcome centre."

A most important factor, again, in bringing expectant mothers to us early in their pregnancy is the fact that they have to apply for a card for their confinements. As I have pointed out, after the card is given they are sent to the ante-natal centre, thus enabling us to examine and keep a watch, during their pregnancy, on all cases that we shall subsequently attend at their confinements. The most important details of these examinations, with any possible difficulties likely to be encountered during labour, are entered on a card, which the student or pupil midwife takes with him or her to the case. It is difficult to exaggerate the importance of this procedure.

Another difficulty I expected was due to competition, mainly that occurring as the result of the Midwives Act. The better class artisan was, I thought, likely to depend on the local midwife. Apart from the long tradition of dependence on the hospital, the poverty of the neighbourhood has helped us, by eliminating largely competition by midwives. Attending the hospital, not only for their confinements but also for all other ailments, the idea of anything like compulsion does not seem to have arisen, and they readily accepted new measures.

Not only has the hospital as a centre helped us in establishing our ante-natal and post-natal clinics, but it affords us another great advantage over clinics not so situated. I refer to the ease with which patients can be sent to the various departments of the hospital for further advice.

As examples of assistance that has been of the greatest use to us I may mention that obtained in the tuberculosis department from Dr. Marshall, and Dr. Hunt's advice with regard to heart cases. I will refer to these again. The facility with which chemical and bacteriological examinations can be made must be mentioned, and also the ease with which any accessory department, such as the dental, can be set up; and last, but not least, the clinic provides invaluable scope for the teaching of students and for research. Whilst the hospital has been of use to the welfare centre, there can be no doubt as to the importance that this centre has been to the obstetric staff of the hospital. The two have helped one another, and through this close association great improvement in the treatment of women during pregnancy and labour has resulted.

Serious operations during the course of and often late in labour, that at one time occurred with comparative frequency, and had to be dealt with as matters of urgency, are now anticipated, and those that are likely to be attended with difficulty are admitted to hospital before labour begins. The importance of this in avoiding any delay in operative procedures is obvious, and not only is unnecessary maternal suffering avoided, but a reduction both of the death rate, and more particularly of ensuing morbidity of mother and child, results. Dr. Eason, the superintendent of Guy's Hospital, in a paper describing the institution and working of the Salomon centre, from which I have most unblushingly stolen what I wanted, concludes with the following paragraph:

"The experience which the hospital authorities have derived from the establishment of the infant welfare centre makes it quite clear that infant welfare centres should, if possible, be closely associated with, or actually established in, hospitals, and that infant welfare centres should in all cases, if possible, include ante-natal clinics, so that the mother and the child can be kept under continuous observation by the same set of medical officers."

In addition to being seen at the infant welfare centre the mothers are visited at their homes by the health visitors, who give them advice as to domestic hygiene and the feeding of the infant. To show the importance of their assistance to the mothers I will only mention the fact that owing to their encouragement 96 per cent. of the women feed their babies at the breast.

It is too early yet to give anything like a statistical history of results, but as seven out of every ten people seen at the centre have been seen before, and as notes relating to them are kept, we should in time have invaluable material.

There are one or two subjects I should like to refer to shortly, and the first of these is heart disease complicating pregnancy. This has interested me considerably during the last two or three years. As showing the importance of the subject, approximately 200 cases have been seen since the opening of the centre. Only a small proportion of these

are serious enough to admit to hospital, the majority going through pregnancy and labour without serious symptoms or risk. It will be interesting to see as time goes on what happens in subsequent labours.

There are a few cases, however, in which the heart is so seriously affected that one anticipates a fatal result, either during labour or shortly afterwards. There is no doubt at all as to the serious effect on the heart of prolonged efforts at expulsion. I used to be asked to see these cases with a view to induction of labour. But I rarely agreed to this. If anything, induction is a more serious trial than labour at term, and I hold the view that those patients who would survive induction would pass equally well through labour at full time, and that those who appeared likely to die in the course of labour were equally likely to die as the result of induction.

I think it was with Dr. French that I first discussed the question of Caesarean section in these cases, over a case of mitral stenosis and auricular fibrillation. From her condition it seemed abundantly clear to both of us that the patient was not likely to survive a labour lasting some hours. I do not think Dr. French imagined that she would stand a Caesarean section, but in any case he thought it would cause less distress. I was more hopeful. I had had some experience in abdominal sections of cases with very bad hearts, and I knew that, provided they were not asphyxiated, they took anaesthetics and stood the operation better than might be anticipated. I found it to be the same in this case. She gave no particular anxiety either during the operation or subsequently, and although when she left the hospital her heart was still very irregular, she was able to walk about without marked dyspnoea. Since then I have performed Caesarean section on a few more cases after consultation with Dr. Hunt.

One case that suffered from paroxysmal tachycardia had severe mitral and aortic disease. Beyond a little bronchitis she did well after the Caesarean section, and suckled the baby. A month later she had an attack of confusional insanity, and ten months later was again admitted to hospital, when she died.

It appeared to me that the very bad cases suffered mainly from mitral stenosis and auricular fibrillation, and, having a talk recently with Dr. Hunt, I asked him what conditions he considered would cause the gravest anxiety as regards labour. He thought that cases with auricular fibrillation, very large heart, and those having very bad exercise tolerance would give the worst prognosis. As regards anaesthetic, C.E. was given with oxygen. The most important thing is to avoid asphyxiation and anything like overstimulation of the heart. I think Dr. Hunt has been as much struck with the results as I have been. The relief to the mothers has been much greater than either of us could have anticipated, and recovery has been speedy. Instead of twenty-four hours, perhaps, of the greatest distress during labour, with death hanging over their heads—and I have little doubt that few of the cases I have operated upon would have survived this ordeal—there has been comparatively little distress for the patients and very little anxiety for those who had to look after them.

Only recently I had a patient sent to me with a history that she had nearly died during her last confinement, that she had adopted precautions against further pregnancy, which, as generally happens in such cases, had failed. She was four to five months pregnant. Dr. Hunt considered that pregnancy should be terminated in the interests of the patient, who was rapidly becoming worse. Induction at this stage of pregnancy is often a tedious business, requiring more than one anaesthetic, and as opening the abdomen allowed me to sterilize her, I did a subtotal hysterectomy. She gave us not a moment's anxiety, which we can usefully compare with her narrow escape at the previous confinement. The results have been such that I shall not hesitate in any future case in which the risks of labour appear to be such that death is likely to result to perform as an alternative Caesarean section.

**Albuminuria.**—Finding albumin in the urine at an early stage in pregnancy, we ought theoretically to avoid the risk of eclampsia. We have not done so. Out of 4,000 cases in the last two years we have had one case. This was a patient who, suffering from chronic nephritis and a high

blood pressure, had in the course of her first pregnancy a stillbirth at seven months.

She was admitted during her second pregnancy at about the twenty-eighth week for albuminuria. This improved so much that she was allowed to go home. She did not carry out the instructions given her, and she came back in a week with eclampsia. The Dublin treatment was employed, but failed to check the fits. Caesarean section was then performed, and the patient recovered. The failure in this case was clearly due to the patient, who, probably tired of the rigid treatment as regards diet endured for some time, allowed herself a little more licence than was good for her. This will probably always prevent us getting those theoretically perfect results I have mentioned above.

The only criticism I would make on the treatment above is this: that I dislike Caesarean section as a late measure when other methods have failed. It has brought it into discredit in the past, and although it succeeded here it generally fails. The vexed question of Caesarean section *versus* the Dublin treatment we still have to leave to the future to decide.

**Phthisis** as a complication of pregnancy presents considerable difficulties. Roughly one can say that whilst some cases became rapidly worse, in others no alteration was perceptible, whilst in a few there seemed to be some improvement even in the general condition.

This vague position has been cleared up for me by Dr. Marshall, and from some notes on the subject he has kindly made for me I select the following. It is in early cases of phthisis that pregnancy produces an exacerbation of the disease. In these early cases the general condition of the patient remains good during the first few months of the pregnancy, and symptoms may even be ameliorated. Deterioration, with pyrexia, wasting, and increased cough, often commences about the seventh month of pregnancy, and there is rapid extension of the disease after childbirth.

A number of cases have been seen during pregnancy who had had pleural effusion or open pulmonary tuberculosis at an earlier date, but in whom the disease had been arrested. With careful supervision most of these patients have gone through their pregnancy and puerperium without any ill effects on the lungs. In a few there has been a lighting up of the old disease, though in most of these cases it has become inactive again under treatment. When the phthisis is of some years' standing and the patient does not show severe toxæmia pregnancy does little harm. There may be a slight increase in pyrexia and sputum at the latter end of pregnancy, but as a rule there is no gross deterioration in the general condition.

It is clear from these remarks of Dr. Marshall's that the cases that call for interference are the early ones, the arrested and chronic cases being allowed to go to full term, rest and extra nourishment being the most important details of treatment. The mother is allowed to nurse her baby if there is no toxæmia. Dr. Marshall holds that the baby is more robust and better able to withstand infection if it is allowed to take its natural food.

For some years past cases have been sent to me from time to time in the early stages of pregnancy, to have this terminated by the induction of miscarriage. It was not long before I discovered that this was a useless procedure. The patients of the hospital class invariably returned, in a few months' time, again pregnant; and even in people of a better class who had been warned of the risks involved, and who had taken measures of precaution against conception, it was by no means uncommon to find that pregnancy had recurred. As a result I refused for a time to entertain any idea of induction.

Another thing I found, which I am glad to see Dr. Marshall agrees with, is that induction either of miscarriage or labour seemed to do as much harm to the pulmonary condition as allowing the pregnancy to go to full term. I am not at all clear as to the reason of this.

As a result of all this I adopted another line of treatment. When it was made clear to me that not only should the existing pregnancy be terminated but that it would be unsafe for the patient to have any children at a future date, I opened the abdomen and emptied the uterus through the abdominal route, sterilizing the patient by removal of the Fallopian tubes. In early cases, in place of this, removal of the uterus by supravaginal hysterectomy can be

considered. Here again, as in heart disease, I was pleased to find that the results were better than anticipated, and attended with less ill effects than appeared to attend induction of miscarriage and labour. Dr. Marshall, who sees these cases over a long period of time, is so satisfied with the results that he states definitely "that the best results are obtained by Caesarean section" (meaning by this the emptying of the uterus by the abdominal route at any time of pregnancy).

I think the number of cases in which an operation is likely to be called for is small, and I still feel that interference in any case should be most carefully considered before it is undertaken.

I have already mentioned that cephalotripsy is becoming an operation of the past. Curiously enough, we have found that when obstructed labour occurs calling for destruction of the infant it is more likely to be found in a multipara than in a primipara. Every now and again a woman of about 40 who has had a series of children born without mishap gets obstruction. This has been explained by saying that the children get progressively larger. I know no very satisfactory evidence of this. It may be due to falling forwards of the sacral promontory owing to increasing weight of body, and possibly to working hard shortly after confinements, when the pelvic joints are still lax. My colleague Mr. McNair suggests that it is due to lack of play in the pelvic joints during labour, the joints becoming ankylosed. We have had one such case recently, in which we performed Caesarean section.

Time does not allow me to go into the question of contracted pelvis. I might, however, conclude with a few remarks on the subject of induction of labour. If one were to classify obstetricians it would be into those who like induction (or say they do) and those who frankly do not. I put myself in the second class.

In theory nothing is simpler. For some reason or another it is decided to induce labour at the thirty-sixth week. When this time arrives a few bougies are introduced into the uterus, and in twenty-four hours labour starts and the child is born without further anxiety. This assumes two things—that we know exactly when the thirty-sixth week has arrived, and that the infant is going to remain the same in size as on the preceding occasion. These assumptions being fallacious, we have to fall back in addition on the rather difficult procedure of estimating the relative sizes of the child's head and the pelvis.

In some cases we find ourselves inducing earlier than we intended, and possibly lose the child from prematurity; in others we have a shrewd suspicion that induction has coincided with labour at term. In one case labour comes off with such ridiculous ease that we wish we had waited for labour at full term; in another we meet with more difficulty than we anticipated, and perhaps lose the child.

Further, instead of labour coming on shortly after the introduction of bougies, it often hangs on for a week or more, to the anxiety of the doctor, the discomfort of the patient, and the mental distress of the relatives, who will not be convinced that everything is right. This operation is, as far as I can gather, an essentially English one, and perhaps the most uncertain and uncomfortable one we possess.

The margin of cases suitable for induction is very small and none too easy to detect. Perhaps its most important indication is in post-maturity. I have always preferred, where possible, to go to full term. It is curious in what a number of cases in which one was tempted to induce labour, the pregnancy is terminated without undue difficulty. In the few remaining one can wait till labour starts, if necessary, and, satisfactory progress not being made, perform Caesarean section; and I do not believe that many of these cases would have proved satisfactory if induction had been performed earlier as an alternative.

As I remarked, I am in a position at the present time to make a few scattered remarks only, and these mainly in reference to recent experience in heart and lung cases. I feel certain, however, that the establishment of these centres has already proved of very great value to us, and that they will enable us in the future to work out the many difficult problems that still confront us in obstetric practice.

## THE THYROID AND MANGANESE TREATMENT IN VARIOUS DISEASES.

(First Report.)

BY

HERBERT W. NOTT, M.R.C.S., L.R.C.P.,  
LITTLE SUTTON, BIRKENHEAD.

In the course of work as a general practitioner cases are constantly encountered, due to some toxæmia or chronic infection which one tries in vain to remove. I noticed that many of these chronic cases presented the signs of thyroid inefficiency, and was thus led to study Colonel McCarrison's well known books, *The Thyroid Gland in Health and Disease* and *Studies in Deficiency Diseases*. As the idea of this treatment was evolved entirely from this study, whatever merit may in the future be found to pertain to it will be due to the vast amount of work he has done.

The treatment consists in the administration of rectal injections of a solution of pure potassium permanganate, of various strengths, given at various intervals, according to the severity of the infection or the length of time it has existed. The standard solution used is 1 grain of permanganate to 1½ pints of sterile warm water, and, as evidence is accumulating that the tablets or solids of the manufacturing chemists are more reliable than are the ordinary commercial crystals of the drug, it should be made from these. As the oxidizing power of potassium permanganate is somewhat reduced by boiling water, a pellet of the drug is crushed to powder in an earthenware basin with a teaspoon or some metal crusher; cold water is poured on to it, and hot water is added to the required volume and temperature. There should be no undue delay in using the preparation, as it is believed reduction in its power takes place fairly quickly on exposure. A metal or painted basin should not be used.

An injection is given with the patient lying on his left side, and it must be administered slowly by means of a funnel and tube or Higginson's syringe. It should be given after the bowels have acted; it should not be used to effect the purpose of an ordinary enema, as it is given with the intention of its being retained.

Patients sometimes have to be encouraged during the first few days, but as they soon feel better they are willing to continue. When subjects of stasis are beginning the treatment, a larger volume of the solution is needed during the first few days until the bowels are cleared. Doses of liquid extract of cascara are given two or three times a day to cultivate an action of the bowels every twelve hours. As the neuro-muscular functioning of the bowel improves, it is more readily stimulated, so that smaller doses of the liquid extract are soon found to be sufficient, until, by degrees, none is required. Those who have difficulty at first in retaining even a small quantity of the solution should remain lying down for twenty minutes or half an hour, when the desire to return it will have passed off. Or, by assuming the knee-elbow position, the fluid runs higher up the bowel, and the desire to void it passes away completely in most cases.

The quantity and the strength of the solution to be used in any given case can only be estimated by experience and by studying the individual. For instance, two doses of a quarter of a pint in the day may be found more effective than one dose of half a pint. In every case it is necessary to warn the patients that they may feel some pain in the epigastrium within a few minutes after the injection is given. It does not last long as a rule, and it is not often complained of after the first few days. They should also be warned that, from three days to two weeks after treatment has commenced, they may pass long white skins or strings of mucus in the stools. Unless this warning is given some may be frightened, thinking they are suffering from tapeworms. Complete mucous casts of the bowel from three to fifteen inches in length are sometimes passed. Eumeshed in these casts enteroliths, and perhaps grape skins, etc., may be seen occasionally.

Thyroid extracts in compressed form, as supplied by most manufacturers, are now very reliable, and these are

given in doses according to the degree of inefficiency the individual shows, or to the inefficiency which can be inferred from his family history. The usual well known signs of inefficiency are depended upon, but when in doubt recent photographs are of value in deciding changes in the eyebrow, in the expression of the eyes, or changes in the shape of the neck and configuration generally. In ladies a hint is sometimes given by hearing that, a few months previously, they had suddenly found their gloves too small, and had been forced to wear a larger size. Or they may, on inquiry, be found to be using cold cream or emollient applications to their thickened eyelids. One-grain doses are given twice daily on the average, but doses of half a grain to 5 or 10 grains daily are in some cases desirable, with proportionate doses in children.

In a very small percentage of cases of rheumatoid arthritis some increase in swelling and pain has been noticed for the first few days after commencing treatment. When this happens it should be stopped for some days; and when resumed the injections should be given alone for three or four days before resuming the thyroid extract.

Another method of administering potassium permanganate in an easily absorbable condition is by cachet. From one-eighth to half a grain of the pure powdered drug is enclosed in the smallest sized cachet. One is swallowed with half a pint of hot water on waking in the morning, when the stomach is empty, and four minutes later, when the cachet will have opened, another long drink of hot water is taken. This is by no means so effectual as is the injection method; but where continuous treatment is desired, and on occasions when injections are not practicable—as, for instance, when travelling—this method will make it possible to continue the course. Very seldom is any sickness caused, but some people appear to be unable to include an egg in their breakfast without feeling sick when this oral administration has been ordered. Nor should more than twenty-one cachets be ordered at a time, for some loss of oxidizing power may result by keeping the cachets too long, especially if exposed to damp.

In every case it is advisable to take the blood pressure before starting treatment. Patients with low blood pressure should be carefully watched in case it is further lowered, when sickness and giddiness may result. This, as a rule, quickly subsides if small doses of tincture of digitalis and nux vomica are given two or three times daily. No case has been recorded yet of anyone being so sickly that the treatment could not be resumed after suspending it for a day or two. Self-administration is easy for some, difficult and impossible for others. Men, if only requiring from three to six ounces of the solution occasionally, can give it to themselves in an upright position and retain it with ease; but women and invalids who are anxious to carry out the treatment themselves will succeed better after they have had instruction from a nurse. Throughout the treatment suitable dieting is of consequence, correction being imperative in cases where diets have been obviously faulty in their carbohydrate or vitamin content and balance.

Having found that this treatment yielded results far better than those obtained by other methods I had previously employed, I sought the co-operation of others in testing it. My object was to ascertain, from the experience of as many doctors as possible, in what conditions it did good and in what conditions it did not. Accordingly a circular letter was sent out setting forth the nature of the treatment, the principles which I conceived to be underlying it, the results I had already achieved, and requesting the recipients to use it in cases of toxic origin, and to submit their results, good or bad, to me. This letter was sent to sixty-eight medical men and specialists in various branches of medical practice, of whom thirty-four were kind enough to employ the method and to post the results. To these whose names appear at the foot of this report I am greatly indebted for their willing and active co-operation. The reports showed that a great variety of conditions had been treated by this method. An informal committee was arranged and the reports were submitted to it. In certain types of cases the results were no better than were to be expected from other lines of treatment; in others the cases were too few at present to enable any appreciation of the value of the method to be

arrived at; while in the remainder the results were such as appeared to warrant the submission of this report. The total number of cases treated by myself and the doctors mentioned is 227.

#### RESULTS OF TREATMENT.

Except where the treatment is being carried out for long-existing chronic disorders, signs of improvement will be seen very early in the majority of cases. For instance, in mild cases of gout with depression and irritability, a change will often be seen in from three to six days. There is an early improvement in the patient's expression, complexion, and mental condition. He feels brighter and more hopeful, even in cases where a long course of treatment may be necessary. The complexion is a good guide. It is not uncommon to see pale, gouty, and livery people take on a healthy appearance within ten days. In the list that follows perhaps the cardiac group showed the most dramatically quick improvement. For instance, all the angorinal cases lost their anxious expression within five days. Even in hopelessly crippled cases of rheumatoid arthritis some degree of comfort is often obtained, with some signs of increase in vigour as their sleep becomes less disturbed.

#### Acute Infection Group.

The cases under this head may be classified as follows.

*Pneumococcal Meningitis.*—A boy, aged 31, had a severe attack of pneumonia and developed meningitis, with typical signs and symptoms. The fluid obtained by lumbar puncture was examined bacteriologically and confirmed the diagnosis. Treatment was begun four days after the report was received, and continued for a week without much change in the child's condition or temperature. During the second week the temperature began to run lower and he was taking food more easily; it was still lower in the third week, with increasing strength and less rigidity, less meningeal cry, and more appetite. The temperature became normal in less than four weeks. At the end of the sixth week he was able to feed himself; rigidity was hardly noticeable, and he played with his toys. He left his bed a month later. The strength of the potassium permanganate was doubled at the end of the third week, with apparent benefit; on an average he received two injections of four ounces of this fluid daily, and they were always retained. On several days three injections were given (whenever a rigor occurred), and he took daily doses of thyroid extract equivalent to 1 grain each week.

*Cerebro-spinal Meningitis.*—A girl, aged 11, was admitted to hospital with a temperature of 101° F. She had been ill for over a week with marked rigidity, and was covered with petechial rash. She showed the gravest symptoms. This treatment was used, and her temperature dropped at once to normal. It was continued for the next ten days, and the temperature did not rise again. The rigidity was passing off on the fourth day, and on the seventh she was able to sit up in bed, with only a few marks left on the skin where severe haemorrhages had occurred. She made a complete recovery.

*Acute Bacillus coli Infection.*—A man, aged 60, had a sudden rise of temperature to 103.2° F. Bacteriological examination of the urine twenty-four hours later showed that he was suffering from a severe infection. Two injections were given daily, from time of onset. Slight signs of cystitis disappeared in three days, and the temperature dropped to normal. A specimen examined sixteen days after seizure was sterile. There has been no return of the disorder during the past four months. No thyroid extract was given during the inflammatory attack.

Two cases of chronic *B. coli* infection are reported as follows:

A lady, aged 29, for two years had chronic *B. coli* cystitis, which had not responded to treatment in spite of treatment in bed with alkalis, boric acid, urotropine, and the usual diet. After three weeks' treatment she began to have less discomfort; six weeks later the pathologist's report showed the urine to be sterile, and it has remained sterile for six weeks.

A man, aged 62, had suffered from *B. coli* infection, with chronic cystitis and occasional rigors, for twelve years. All treatments, including vaccines and urinary disinfectants, had proved useless over a long period. He began treatment eight months ago, during a rigor, when his temperature was 103.2° F. The temperature sank below normal in two hours. He has continued treatment for six months, and has had no rigors or cystitis, but finds it necessary to continue the cachet method of treatment daily, together with his thyroid extract; for, if discontinued for a few days, pelvic discomfort returns, with neuritic pains in the legs. His anaemic complexion has become a healthy, ruddy one; his hair has grown considerably, whereas he had been very sparsely covered for some years.

#### Diseases of Joints.

Recent infections of joints are often rapidly controlled, whereas long-standing cases of chronic arthritis with deformity are difficult to influence for the better, if at all. The number of cases treated in this group was 36 (acute rheu-

matoid arthritis 3 cases; chronic rheumatoid arthritis 33 cases).

**Acute Rheumatoid Arthritis.**—Of the three cases in this group all were cured. If the complaint has only been present for two or three weeks two injections daily, for five or six days, will sometimes arrest it; and when continued once a day for the ensuing week, and on alternate days during the third week, the joints may be found quite normal and free from pain. This rule also applies in cases when an acute infection has occurred upon long-standing disease. The increased pain and swelling of the fresh infection will often quickly disappear; and, in some cases, the improvement will be continued to a point of a reduction being made in the original deformity. The following case is recorded as an example.

A woman aged 49. Her trouble began four weeks previously with a rise in temperature to 101.2° F., with diarrhoea, supposed to be due to a chill. No notice was taken of it. Three weeks later the finger-joints, wrists, and knees became much swollen and painful; there was a slight temperature. She had been very anaemic for fifteen years, for which she was frequently treated without success. After eight days' treatment the swelling and pain had gone, and her anaemia had been replaced by a good colour, which she has retained, without any return of the pain or swelling, for the past six months. The treatment was continued in her case for three weeks in succession.

**Chronic Rheumatoid Arthritis.**—Of the 33 cases reported 8 were cured, 14 relieved, and 11 not improved. Some cases of many years' standing can be expected to improve greatly. Much will depend upon the general condition of the patient's health and the degree of deterioration which has occurred, as evidenced by radiograph, and on the degree of ease and rest obtainable by the patient during treatment. Careful nursing homo type of management will give better results than irregular domiciliary treatment. Much, too, will depend upon the individual's temperament. Those who are patient and submit to care, with restricted dieting, will do better than the impatient.

A woman aged 51. Watched for eighteen years, with slowly progressing increased swelling of joints, chiefly affecting the finger-joints and knees. She had difficulty in walking and rising from her chair. She was often treated with courses of thyroid extract without benefit. She paid many visits to spas, and had electrical heat, vaccines, and other treatments. After three months' treatment her hands are much more comfortable, the knees less swollen with freer movement, but bony alteration precludes perfect movement ever being obtainable.

#### Heart Diseases.

Three cases of cardiac failure are reported (the ages ranged between 65 and 73) with advanced anasarca, and described as "in extremis"; they had ceased to react to tincture of digitalis; rapid relief ensued a few hours after the first injection. The dropsy disappeared quickly, and all of them were able to leave their beds after one week's treatment. With the help of small doses of tincture of digitalis and one injection weekly they have been kept comfortable, able to move about their houses, and, in one case, do some light work in the garden for a few hours each day.

**Cardiac Asthma and Dropsy.**—A woman aged 66; a very serious and advanced case. She was striving for breath, and was loaded with dropsy to the extent of hard board-like abdominal walls. There was no valvular lesion; no albumin in urine. The pulse was small and running. She was pale, cyanosed, and looked anxious. Albumin had been present in large quantities, three months previously, when a milder degree of cardiac asthma was noticed and warded off by rest in bed for five weeks. One injection of half a pint of the standard solution was given and retained for ten minutes. It was quickly followed by free diuresis, and the asthma was noticed to be lessening in from three to four hours. A second injection was given twelve hours later. Diuresis continued, and asthma was hardly noticeable at the end of twenty-six hours. Two more injections were given during the next twenty-four hours; then one daily for four days, when no dropsy was visible. She was out of bed and walking in her room on the seventh day. She was given 1 grain of thyroid extract twice daily, and tincture of digitalis, *n.x.*, twice daily. A weekly injection is found necessary to keep her free from dropsy.

**Angina Pectoris.**—Five cases are reported; all of them were cured; four were diagnosed by well known consulting physicians. They were in various stages of the complaint, one having suffered from the disorder for over five years. All obtained relief in less than one week. In two of these cases, where injections had been regularly carried out twice daily, relief from pain and oppression was experienced in

four days. Seldom do they find it necessary to resort to their customary remedies as time goes on.

A woman, aged 52, had suffered from "indigestion" and muscular rheumatism for many years. She spent most of last winter in the South of France, chiefly in a nursing home, lying in bed for many months, and was definitely declared to be suffering from angina. She was brought to this country as a "cot" case. It required very little exertion to bring on the pains, and she was seldom if ever free from the anxiety and feeling of cardiac oppression experienced in this disorder. The feeling of oppression and dread had almost entirely gone after four days' treatment. At the end of three weeks, with two injections daily, she had only experienced one slight attack of pain since it was begun. Her colour began to improve about the tenth day. Nine weeks after beginning treatment she had a very good colour and was able to take longer walks than she had done for some time. As there was a history of myxoedema and other signs of advanced subthyroidism in her family, her dose of thyroid extract was increased to 5 grains after two weeks' treatment. At the end of seven months' treatment she still continues to take the same dose of thyroid extract and an injection every third or fourth day. She has no signs whatever of angina, and is living a healthy out-of-door life.

#### Disorders of Pregnancy.

**Morning Sickness.**—Four cases of this disorder are reported as having done particularly well. One was showing alarming symptoms. She was a primipara, aged 23, whose vomiting had become so severe at the end of the third month that even drinks of water were being returned. After one injection a great improvement was noticed; and after three days' treatment she was able to take ordinary diet. This method is not so successful in cases where the sickness has developed in the later stages of pregnancy.

**Eclampsia.**—One case of this condition is reported as follows:

A woman, aged 26, was found with a white swollen face and distorted eyelids. She was holding her head and complaining of terrible headache. She said her sight was affected and that she was going blind. She was slightly delirious, had not slept for fifty-six hours, and had been perambulating the room for two nights. She had been vomiting frequently for two weeks, and had suffered from occasional nose-bleeding. Her limbs were dropsical, deep pitting being made by pressure over the tibia; she was expecting her confinement in a month. An injection of 2 grains of potassium permanganate in 14 pints of water was given at once. She retained a pint for ten minutes. She left the bed and returned the injection followed by a chamberful of urine. She immediately declared her headache had gone; she said she could see quite well, took a drink of milk, and fell asleep twenty minutes after the injection was given. She was awakened every two hours for a similar injection. Visited seven hours after the first occasion, she was found sitting up in bed, drinking a glass of milk, smiling, and said she felt better than she had done for weeks. There was only slight evidence of puffiness in her face, and no pitting could be obtained over the tibia on pressure. Nine hours later she was confined, without giving any concern to the nurse or trouble to herself. The urine, tested before the injection was given, contained only the slightest trace of albumin; there was none on the following day. She received an injection twice daily for a week, and a daily injection was given for one month. The infant thrived very well.

There are two cases of the pre-eclamptic condition. One is reported in the following words:

A woman aged 30. After her last confinement she had a large haemorrhage which had left her very anaemic, with breathlessness and oedema of ankles and legs, with a large amount of albumin in the urine. She was apparently not treated for the condition, and came with the above symptoms when eight months pregnant. Injections were given, and thyroid extract 5 grains daily. After one week the urine contained only a trace of albumin, and the oedema had gone. The general condition gradually improved. She was delivered at full term of a healthy child, without complications.

The second case is more interesting, as she had suffered from actual eclampsia with convulsions over her confinement four years previously. She was carefully watched throughout her seventh and eighth months. Early in the ninth month she had feelings of dizziness with headache. The urine contained a slight amount of albumin. She was immediately treated with injections of the standard solution, twice daily for three days. She could not retain more than half a pint. The headache, dizziness, and albumin disappeared on the third day. The injections were given once daily for the following ten days, and continued every third day till she was confined. On this occasion she has had an abundant supply of breast milk, and a contented infant whose weight has increased by 1 lb. in his first twelve days of life. Over the previous confinement she had a poor secretion of milk, and, as the child did not thrive, weaning was required at an early date.

#### Disorders of Metabolism.

**Acute Gout.**—The following case, in which the condition had been present for many years, is reported.

A woman, aged 66, had often attended over a period of twenty years for acute attacks of gout, accompanied by gouty patches of eczema, chiefly affecting the shins. Recovery under ordinary treatment was slow, and there were early recurrences. Three days after

treatment was begun the vividness of the blush and area of the eczema were reduced by nearly one-half. The swelling and pain of the ankle-joints had entirely gone by the end of the first week. In less than three weeks a normal condition was restored. She has had no return of the complaint at the end of six months, and she keeps the eczema in abeyance by one or two injections each month. No alteration was made in diet, or other remedy used.

**Diabetes Mellitus.**—Two cases of this disease are reported as follows:

A man, aged 54, had been under treatment and observation for four years when the onset of disease was first noticed. Throughout this time his weight had very slightly varied between 12 st. 10 lb. and 13 st. 3 lb. On May 17th of last year he suddenly became much weaker. He lost 11 lb. in weight during the last three weeks of May, and was confined to bed for about ten days. He looked as if insulin would have to be given at any time, and had heavy acetone odour in his breath, and a constant cough. The treatment was begun on June 1st, and in sixteen days his weight had increased by 10 lb., while still on his usual diabetic diet. His colour and vigour rapidly improved, but there was no alteration in the percentage of glucose. Seven months later he is found ruddy coloured, 15 lb. heavier than he was at the end of May, with still no change in percentage of glucose. This result is the more interesting when it is considered that he took 2 grains of thyroid extract daily for the first two weeks of treatment. Another significant feature about his case was the quick relief he had from a persistent pruritus from which he had suffered for some years before he developed glycosuria.

A woman, aged 63, with 6 per cent glucose, and who has persisted in taking ordinary diet during the last three years, in spite of her disorder, has increased her weight by 4 lb. after seven weeks of the treatment, taken in the cachet form. The percentage of glucose has been reduced by half. No thyroid extract has been given in this case.

#### Disorders of the Digestive System.

**Gastric Ulcer.**—The following two cases of this condition are reported.

One, a man aged 53, who had a very severe haemorrhage in December, 1916, and who had the operation of gastro-enterostomy in the following month, was taken in hand immediately after a severe haemorrhage in August, 1924. He had had a similar recurrence in August, 1922, from the effects of which he took nine weeks to get over. Injections in the latter recurrence were given twice daily, and no other treatment besides careful dieting and a few doses of morphine. He left his bed at the end of a month, looking very much better than he did after the attack in August, 1922. Injections have been continued, once weekly, for the last three months. He is looking stronger, and is weighing heavier than he has done for the past five years. His diet has not been restricted in any way, and he is taking cod-liver oil, with occasional doses of a finely graded powder containing sodium bicarbonate, calcium carbonate, and magnesium carbonate, 20 grains of each, occasionally after meals.

The second case is a young woman who was treated by this method within an hour of her haematemesis. She did exceedingly well; left her bed on the seventeenth day, and has remained well for the last six months.

**Colitis.**—Five cases, all reported cured on an average in three weeks. One of these cases, a woman of middle age, had suffered very severely from the complaint for over two years.

#### Nervous Diseases.

**Infantile Convulsions (Post-convulsive Condition).**—The following case is reported of a male infant who was seen one and a half hours after having had convulsions.

A well developed child, aged 9 months, with no history of illness except slight diarrhoea during the past three days, with restless nights. When seen he was very excited and screaming; there was no rise of temperature. Two ounces of the standard potassium permanganate solution were given and retained. The screams and excitement stopped suddenly in two and a half minutes. His expression altered completely, and he became quite calm, smiled at his mother, his mother's knees his eyelids began drooping and he fell fast asleep within seven minutes from the time the injection was given. He remained asleep for three hours, woke up calm, and after having sent to sleep, remained asleep for eleven hours, and when seen being better than he had been for a week. He was described as 'other remedy has been needed during the two and a half months which have elapsed since this seizure.'

**Chorea.**—A girl, aged 7, was quickly relieved of all symptoms after injections had been continued for from three to five weeks. She was the fourth of her family to be affected with the complaint, and her eldest sister had died of it, owing to cardiac involvement.

**Sciatica.**—Six cases are reported—three cured, two much improved, one slightly improved.

A man, aged 39, with twelve years' history of fibrositis in deltoids, infraspinati, and hamstrings. Relieved temporarily by courses of massage, etc. No evidence of infection in the accessory sinuses or teeth. Slight constipation. Blood pressure 110 mm. of mercury. After three weeks' treatment (during which all other treatments were stopped) the pains improved. After five months' treatment he is now more comfortable than for the past twelve years, although there is occasional discomfort in the hamstrings. (This is a doctor's description of his own case.)

#### Pulmonary Diseases.

**Chronic Bronchitis.**—Eleven cases have been reported, some of them accompanied by bronchitic asthma. All are described as considerably improved. One observer expresses the opinion that the treatment, in some cases, seems to act in preventing catarrhal conditions of the mucous membrane extending. Six of these cases are reported as having had the character of the sputum altered, a purulent appearance having become lessened in each case, though no bacteriological examinations have been carried out. The opinion seems to be that the younger cases obtain very great benefit, and are likely to be cured; the older patients are relieved considerably—they have less cough, less expectoration, and more rest. Their coughs are stronger, they can get rid of the expectoration more freely, and they are noticed, when moving, to be less wheezy. The patients express satisfaction—they feel better and stronger, and do not require so much "cough mixture."

**Asthma.**—Six cases are reported as having been cured, or relieved almost to the extent of cure. In the opinion of two observers the treatment acts as a preventive in the development of the complaint, when used early enough.

#### Skin Diseases.

A case where the condition of the foreskin and glans penis of a man, aged 61, was giving grave concern to those in attendance, on account of its malignant appearance, is reported as follows:

He had been suffering from a chronic balanitis for many years. For fifteen months before this treatment was used several different local applications and tonic remedies had been ordered without effect. The foreskin had become dull red coloured, indurated, and friable, with complete retraction impossible. The glans penis had developed several ulcerated, peduncular excrecences on its surface. By the end of nine weeks' treatment a normal condition was restored. A change began to be seen after two weeks' treatment. The colour and induration began to improve first; two weeks later a more velvety condition of the skin was noticeable, and all signs of discoloration had gone, as also the ulcerations.

**Chronic Seborrhoea.**—Several cases, both of the dry and moist variety, have been reported cured, and others relieved, whilst under treatment for various disorders. This has been accompanied by increase of hair in the baldness of men, and an increase of growth, with a healthier appearance of the hair, in women; this has been seen at various ages up to 70.

**Pemphigus Foliaceus.**—One case, in a woman aged 35. She had taken thyroid extract, and had been in a nursing home for close on four months, many remedies having been tried with little success. In less than a week after commencing thyroid extract accompanied by injections of potassium permanganate she began to improve and made a complete recovery.

**Acne.**—Four cases: three cured, one improved.

**Acne Rosacea.**—A man, aged 38, had suffered from this complaint since the age of 16. All forms of treatment had been used throughout his life. He improved slightly in hot weather, but in winter existed as a severe and disfiguring case. After two months' intermittent treatment there was very slight trouble this winter. (This is a doctor's description of his own case.)

**Varicose Ulcers.**—Three cases are reported, all of which healed rapidly.

One, a large ulcer on the lower third of the leg, which was very septic and odorous, and which had existed for over two years, was clean-looking and odourless in four days. At the end of a week large and vigorous granulations were seen to be springing from the base. At the end of two weeks the ulcer was covered with healthy skin in its whole extent. The granulations began to heap in the centre, and the ulcer was irrigated twice daily by a weak solution of permanganate. Rapid subsidence of the granulation occurred, and a healthy integument.

ment had spread across by the end of the fourth week. No other treatment was used with it except a little boracic ointment and light bandaging.

### Goitre and Myxoedema.

**Myxoedema.**—Three advanced cases of this complaint seem to require less thyroid extract than the average dose which is given to keep such cases in moderate health. What is chiefly noticeable is that they have some colour in place of the usual anaemic appearance presented by those receiving thyroid extract only.

**Parenchymatous Goitre.**—Four cases are reported to have quickly responded to the treatment, two of them without the use of thyroid extract. One is inclined to relapse, unless she keeps up the treatment occasionally.

**Exophthalmic Goitre.**—Three mild cases find themselves very much better, with increased weight, and diminution of symptoms, after a few weeks' to a few months' treatment. Two advanced cases describe themselves as "less nerry," and the swelling of the neck has diminished in size. One case of enlarged thyroid gland is reported as having been on the point of having the operation of thyroidectomy, but shortly after the treatment was used operation became unnecessary. In another very severe case no relief at all was obtained after five weeks' continuous treatment, with injections.

### Diseases of the Breast.

**Chronic Mastitis.**—Three cases are reported. Two had been operated upon during the previous two years. One had a severe recurrence in the affected breast, which disappeared entirely by this method of treatment in eight weeks. The other had both breasts badly affected. In this case complete disappearance resulted after less than seven weeks' treatment. The third case is interesting, inasmuch as, after seven weeks' treatment, a small cyst became easily discernible in place of a thickened tender mass which had existed at the beginning of treatment; but this cyst disappears, and the tender mass returns, on cessation of treatment for six to eight weeks. She also develops a typical chlorotic lemon-coloured complexion whilst the mastitis increases in size, but after seven daily injections her complexion clears and some colour appears in her cheeks. She is also interesting, inasmuch as her defective hearing is almost normal whilst she is taking the treatment, but she loses her hearing very soon after the treatment is stopped.

### Composite Cases.

The following three typical examples, in which more than one pathological condition was present, are reported.

1. A man, aged 44, presented himself last September with a large pustular swelling in the left axilla, which required the usual surgical help. He was noticed to be paler, thinner, and with a more haggard and anxious expression in his face than was justified by knowledge of his circumstances and surroundings. He was also suffering from, and receiving treatment for, pain of pyloric origin after meals, for pruritus and of a persistent nature, for heavy acne of the back extending from the neck to his waist, for which he had received many courses of autogenous vaccines and other remedies, and his scalp was so persistently irritable that shampooing was required weekly. Quick relief was given to the pruritus first; the indigestion disappeared at the end of the third week; threatening pustules in the axillae were found subsiding about the end of the fourth week. His head required less shampooing a few weeks later; his acne is now quiescent. His colour and expression have improved and his weight has increased by 7 lb. Beginning with two injections daily, he finds now that one every third or fourth day keeps him comfortable.

2. A married woman, aged 25, had been anaemic since the age of 16. At 19 the anaemia was more profound, in spite of treatment. From the age of 20 to 25 she had been listless, tired, always suffering from asthmatical bronchitis, and had a woe-begone expression, with black rings under her eyes. She married three years ago and all the symptoms became intensified, to which was added a heavy leucorrhoeal discharge. Suspected to be tuberculous, she was further depressed by the thought she might have to enter a sanatorium. Beginning treatment last August, some colour was visible in her cheeks in nine days; the leucorrhoeal discharge was much lessened in a fortnight; vigour was returning; the cough and expectoration were less noticeable at the end of three weeks. Treatment was continued throughout the autumn, and when seen at the end of December she was hardly recognizable. Her weight had increased from 6 st. to 7 st. 1 lb.; her bronchitis and leucorrhoeal discharge had entirely disappeared; her face was full and round, her complexion better than the

average woman of her age; her hair was healthy and her eyes brilliant. She gave up dancing at the age of 18; this winter she is attending two dances a week.

3. A married woman, aged 24. Similar case to the above, but with the added infirmity of periodic fits of sneezing. Life had been made miserable by fits of thirty or forty sneezes in succession, often interfering with sleep. This had been going on for four years, in spite of the use of the electric cautery, which gave only a few weeks' relief when resorted to. These troubles have been removed, including the fits of sneezing, after three months' treatment.

### A WARNING.

By a method of treatment so easy and so cheap it will be readily understood that temptation exists for patients to pass on their prescriptions to friends. The writer knows of many instances of this, and he knows of many nurses having undertaken the treatment of cases similar to those they have attended under instruction. Irresponsible and ill judged treatment, given in this manner, is certain to lead to disaster at some time, for these two drugs can produce poisonous symptoms, as we all know. Besides which, if secret and uninstructed use is being made of this remedy, we shall be liable to be called to sickly, cyanosed, and collapsed individuals, who never were subjects fit for the treatment from the first. The writer is of opinion that those who prescribe it should order only a few pellets of the drugs at a time; that the prescription should be marked "Not to be repeated"; and that a copy of it should be kept for reference, as a check on the number of pellets used. In all cases it will be advisable to write instructions carefully, explaining how much of the standard  $1\frac{1}{2}$  pints of solution is to be injected on each occasion, and how often in twenty-four hours.

In a very small percentage of cases peculiar little local infections seem to become activated. People who are not in the habit of developing pustules or small boils will occasionally be found with a diminutive boil or two on their scalps, or somewhere on their bodies. These clear up quickly; nor has there been any need to stop the treatment, for wherever they have developed the individual patient has been one who has gained great relief from the treatment eventually. In this connexion it will be remembered that in his book *The Parathyroid Glands in Relation to Disease* Vines states that occasionally, when using parathyroid therapy in chronic infective states, certain septic foci have appeared to be activated which had shown no evidence of existence before the therapy was used, and this is perhaps what happens when the potassium permanganate is used in conjunction with thyroid extract.

In addition to the cases here noted I have received reports on a certain number of others which may be roughly classified as follows: Gynaecological, obesity, chronic gout, acidosis in children, pyloric spasm, chronic alcoholism, high blood pressure, epilepsy, neuritis, migraine (improved), lupus erythematosus, alopecia areata, seborrhoeic eczema, psoriasis, and certain eye diseases. These cases, some of which are as yet incomplete, I hope to report in a later communication.

The following is a list of the doctors from whom I have received reports of the results they have obtained with this method of treatment:

- |  |   |
|--|---|
| Dr. E. H. Crisp, London.                               | Dr. W. A. Newall, Chester.                    |
| Dr. Cyril Dobie, Chester.                              | F. G. Norbury, F.R.F.P.S.,<br>Chester.        |

## PEPTONE AND SERUM PEPTONE IN ASTHMA.

BY  
A. G. AULD, M.D., D.P.H.,  
LONDON.

IN this paper I wish to put on record a few points on the peptone treatment, and to add something on serum peptone in asthma.\* A note on the latter was published by me in this JOURNAL on September 27th, 1924.

Peptone acts by changing or desensitizing the interior of the body, so that the disease has little chance of attacking. It is found that some persons are better for this purpose than others in whom the anti-anaphylactic reaction is defective or even wanting. Those who have had much disease, and especially suppurative lesions, are resistant. The peptone (Armour's No. 2†) is given usually intravenously, and slowly, and when the patient is as free from asthma as possible. It has been stated by several observers (who have not used this method) that the intravenous use is dangerous. I may therefore affirm that in the thousands of injections I have made with this peptone there has never been a single case of accident. I must claim it to be absolutely safe, even for the youngest child. In some cases, certainly, the peptone may be given intramuscularly in doses of 7.5 per cent., especially in children and old weakly people. When this does not act satisfactorily, however, the intravenous use of the 5 per cent. solution should be made.

As a general rule, peptone overcomes any tendency to asthma derived from foods and animal epithelial substances, though if the latter be found it ought to be got rid of as far as possible. At the same time, peptone fails to affect the skin reactions. This is in contrast to what occurs after a pyrogenic dose. A young man gave a severe reaction to horse dander. He was treated (not for this) with typhoid vaccine, intravenously, which raised his temperature to 104° F. Next day it had fallen to subnormal, when the skin reaction to horse dander had entirely disappeared. This shows that a great desensitization had taken place, but the skin reaction shortly returned. Again, with small doses of peptone, the endothelial cells of the capillaries are first rendered slightly more permeable, quickly followed by a "blockade" in which the lymph is less and gets less concentrated to 9 per cent. below pre-injection level (Petersen<sup>1</sup>). The pyrogenic reaction, on the other hand, causes large molecular aggregates to pass through for a long time.

The skin reaction to peptone may be useful before beginning treatment, although I have had cases which contradicted it. Intravenously, 5 minims of the 5 per cent. solution is an excellent beginning, continued twice a week by an increase each time of 3 minims, until 26 minims (1.5 c.c.m.) are reached. Continue the last dose for two more doses, which makes the tenth dose. By this time it will be found that there are three classes of cases. In one the patient is quite well, and usually expresses surprise at his condition; in another he is much better, but not yet well; and in a third he is but little better. In the first class it is only necessary to increase the dose by about 4 minims for two more doses, and then giving weekly 25, 15, and 10 minims, when the treatment is finished. In the others, if the patient is standing the peptone well, go on increasing the dose to 2 c.c.m., then 2.5 c.c.m., or in some people even 3 c.c.m.; then reduce weekly by about 10 minims to 33, 23, 13 minims. If, however, during this time the patient has an attack of asthma, reduce the dose considerably, say to 25 minims. Continue about this for two or three weeks, then reduce weekly to 15 and 10 minims. When the patient is weak and has severe attacks, the dose must be kept low. Failure with the peptone treatment is more often due to the practitioner's want of realizing the needs of a case. Each case requires careful watching, and sometimes one finds that thyroid extract (1 grain daily) or iodine (in hyperplasia of thyroid) or ovarian substance (5 grains) at the menopause, are all useful.

Some of these points may be illustrated by a few cases in which it is unnecessary to give the clinical details.

\* This substance has been successfully used in other allergic conditions. † This peptone is used because it contains the correct quantities of proteose, and is free from histamine. Witte's peptone, which contains histamine, should not be given intravenously.

## CASE I.

A lady, aged 53, began to suffer from asthma after influenza four years ago. The attacks were very sudden and severe, and were getting worse. She was sent to me by Dr. Windle of Southall. I gave her peptone up to 26 minims intravenously, and during this time she had no attack of asthma. She then got about 30 minims for a week or two, and it was reduced by 5 minims a week to 10 minims. Part of this time she was laid up with an influenza cold and high temperature. No asthma resulted, and she remains quite well.

## CASE II.

A lady, aged 39, had severe asthma since 1913; an enormous quantity of expectoration accompanied it. She also had hay fever as long as she can remember. She was sent to me by Dr. Hackett-Overy. She had the same treatment as the last case and has never had the slightest asthma since. She had an enlarged thyroid, which was improved by iodine in small doses.

## CASE III.

A man, aged 41, who had had asthma from the age of 5, was sent by Dr. Morley of Mill Hill, who had treated him with some intramuscular injections of peptone some time previously, which had benefited him considerably. His mother had asthma, and he himself has it every night. During the first nine intravenous injections he was quite well and had no nocturnal asthma. Then he took slight asthma, when the dose was reduced. This passed off, and the dose was slightly raised until in about a month he was able to take the usual dose, about 2.5 c.c.m. During this month he was practically quite well and had no asthma. In the following month he got weekly small doses and is now quite well, and feels very fit during the day.

Sometimes the peptone acts very quickly, as in the following case.

## CASE IV.

A lady, aged 51, who had been confined to bed with severe asthma for about three months, whom I was asked to see by Dr. Mould of Oakham, after the first injection or two of peptone entirely lost her asthma and got up. She also had 1 grain of thyroid a day and 5 grains of ovarian substance, as her menses were scanty and irregular. Dr. Mould has written that she "never has an attack of asthma, her chest is quite clear of râles, the pulse rate is normal; walks now three or four miles a day, and is getting stouter."

When bronchitis is present a vaccine may be considered. In this case first give peptone for about two weeks, which will render the patient well able to stand the vaccine, to which asthmatic patients are often very sensitive. This effect of peptone has been clearly demonstrated by Warren Crowe.<sup>2</sup>

Many asthmatic patients vomit when the attacks come on, and this often gives relief. There may be a rash also. These symptoms show the presence of a poison. But we are to a large extent ignorant of the mode in which peptone acts, especially when we consider the rapid cures, lasting a long time, produced by very small doses. The histamine fraction in Witte's peptone I held to be entirely useless,<sup>3</sup> and this has been confirmed by Abel and Geiling,<sup>4</sup> who found that only the alcohol-insoluble portion produced immunity. Evidently the passage of peptone into the blood is all-important. The proteoses do not enter the blood when swallowed. Vivi-diffusion experiments by Abel and others have shown amino-acids and also a non-soluble proteose in the blood, a proteose united with protein. This does not come from the alimentary canal, and when peptone is swallowed, especially when it contains some histamine, the effect is a considerable secretion of gastric juice, which is of importance in dealing with injurious substances.

## SERUM PEPTONE.

In 1922 Dale and Kellaway<sup>5</sup> found that the normal guinea-pig's serum (2 to 5 c.c.m.) could, after about two hours, protect a sensitized guinea-pig from an otherwise fatal dose of antigen. Dale thought this power was due to a detachment of antibodies from the cells into the blood; but some time afterwards Kellaway and Cowell<sup>6</sup> found this was not so, but that an entire disappearance of antibodies occurred from both cells and blood. Working also with Armour's No. 2 peptone, they found that in guinea-pigs sensitized to horse serum the circulating antibodies were reduced to one-third, while the tissue antibodies were unaffected. In the latter case, although the conditions for intoxication appeared to be unique, the animals withstood a dose of antigen two to three times above a lethal one for the sensitized guinea-pig. Now in man we do not get much result from the injection of 2 or 3 c.c.m. of his own serum (a quantity in any case too small), but when his blood is incubated with peptone *in vitro* a change occurs in the serum and the peptone which renders the mixture highly suitable for the treatment of asthma.

When blood is drawn from a patient it becomes altered in quality just before it clots, getting temporarily poisonous. If, to the freshly extracted serum, agar, starch, or peptone be added, and the mixture incubated at 37° C. for an hour or two, the poisonous quality becomes greatly increased and permanent, owing to the production of anaphylatoxin. In making serum peptone it is always the patient's own blood that is used, more especially just previous to an attack. At first I tried adding peptone to the prepared serum and incubating, but I found that mixing the patient's blood with the peptone and incubating at 37° C. was best. The peptone solution (Armour's No. 2) is prepared by making a 10, 15, or 20 per cent. solution in physiological saline (10 c.cm.). The patient's arm is bound above the elbow, and a two-inch serum needle, over the end of which a small (two-inch) piece of rubber tubing is drawn, is inserted into a vein. The peptone tube is held under the tubing, and in about a minute 30 c.cm. of blood will have flowed into it, the tube being shaken gently all the time, then turned and twisted so as to mix the blood and peptone. If the vein is not prominent, or the blood comes only slowly, a 20 c.cm. syringe may have to be used. The tube, well sloped, is then put in the incubator at 37° C. for a few hours, or until the serum peptone has separated out. It is then removed and kept at room temperature until next day, when the serum peptone will appear as a clear solution, which is carefully poured (except the last part) into a bottle. If acid, it is neutralized with soda, and 0.5 per cent. phenol is added. From the 40 c.cm. about 14 to 18 c.cm. serum peptone will be obtained. Both the bottle and tube may be left for another day, if necessary, and pipetted or re-poured out. No measures involving any speed are adopted.

The 10, 15, or 20 per cent. solutions of peptone are made according to the case. In weakly delicate persons, having severe attacks, it is well to begin with the 10 per cent. and increase upwards if necessary. With strong persons the 15 and 20 per cent. solutions are used. Nory and de Kruij state that serum much reduces the potency of peptone, and that the anaphylatoxin makes up for this reduction. Now it must be remembered that a 10 per cent. peptone solution represents 2½ per cent. over the whole mixture and the 20 per cent. represents 5 per cent. But whether the resulting serum peptone contains more or less we cannot tell as they are so combined. It is nevertheless true that 2 or 3 c.cm. of the 20 per cent. mixture does not produce reactions in man as a rule. The dosage is as follows when the patient is as clear of asthma as he can be: 0.5 c.cm., 1 c.cm., 1.5 c.cm., 2 c.cm., 2.5 c.cm., 3 c.cm., given twice a week intravenously. If the higher doses produce any reaction, reduce it slightly. Then give 2.5 or 3 c.cm. for two weeks, and 1.5 c.cm. one week, and 1 c.cm. the next week. The latter doses are given once a week. This is, of course, only a general statement. Great variations may be required.

This solution is used for cases which have not proved satisfactory to peptone alone. Of these I shall give a few.

## CASE V.

A gentleman, aged 35, at the end of the war had been in Durham. He had had asthma since 1903. In 1908 and 1909 he had operations in his nose; these had no effect on the asthma. In Durham his asthma was very bad, and Dr. Thomson treated him with vaccines (autogenous) from the chest and also from the intestines. This gave him relief for two or three weeks. He was going then to England, and Dr. Thomson advised him to see me. I found him a healthy-looking man; he gave some reaction to horsehair and to pollen. I treated him with peptone, which suited him very well, and it kept the asthma away for about six months. Every six months he used to return for some more injections. Last year he got serum peptone—at first six injections, then after a little time he got eight injections. At first the chest was troublesome (for about two weeks), then the asthma entirely disappeared, and he has never felt so well as now.

## CASE VI.

The next case is altogether different. A man, aged 50, suffered very badly from asthma for years. He was very stout; he weighed 14 st., and had been 19 st. He looked healthy, but was very subject to bronchitis. In 1917 he was advised to leave London for Devonshire, where he was better of asthma till August, 1920. Dr. Erskine-Collins of Watchet, Somerset, sent him to me, after failing to do him much good. He remained in London and I gave him eleven intravenous injections of serum peptone, after which he was much better and returned home. He has since written me to say that he is feeling very fit, and except for some morning trouble is practically free of asthma.

## CASE VII.

A little girl, aged 11, was sent to me by Dr. Dunlop of Crouch End. After treatment with peptone her asthma greatly improved, but still she had a little. During the summer it returned somewhat, after the holidays, when she was put on serum peptone. The result was that she lost her asthma and continues well.

There are cases of asthma which prove very stubborn, and of such is the following one:

## CASE VIII.

A lady, aged 53, was sent to me by Dr. Swindells of Grimsby. She had had asthma since 1909. Her father, grandfather, and grandmother all had asthma. She was thin and cachectic-looking, and had some cyanosis of her lips. She breathed asthmatically, and told me she was never really free from asthma. Now, without going into particulars, it may be said that Dr. Swindells tried peptone without avail, and then the serum peptone was used and given by her doctor for over three months, with moderate benefit.

The following may be added:

## CASE IX.

A lady, aged 57, about fourteen years ago had asthma when in Greencock. The asthma was very severe. No effect from injections received at the time, nor afterwards. She was an intense sufferer, and went to live in Leicester in June, 1924. In July she saw Dr. Greer, who sent her to me. I asked him to try her with peptone, which he did, but gave it up as she was no better. She then came back, and I made serum peptone, which was sent on to Dr. Greer with instructions as to its use. Notwithstanding, she had several bad attacks the first two or three weeks. She then returned, and a fresh lot, stronger, was made, which was sent on to Dr. Greer. Then the asthma stopped entirely, and except for about one or two attacks she has been quite free. "She feels much better, sleeps soundly, and has no asthma."

## CASE X.

This is the case of a boy, aged 6½. He was sent on from Sheffield by Dr. Young, with a history of asthma since the age of 9 months. The attacks last three days, and come on about every three weeks. He was a healthy-looking boy. Dr. Young was asked to try peptone, which he did, but the boy took his usual asthma attack just the same. The peptone, however, was only given a month, when he returned here, and I made serum peptone and gave him five injections. During this time he had no asthma. He then went north and took the serum peptone with him, which was given by Dr. Young as prescribed till finished, 1.6 c.cm. being the dosage. The boy has since been quite clear of asthma.

I may now add a case which shows that serum peptone may act quickly:

## CASE XI.

This is a lady, aged 58, who has been subject to asthma for many years. She consulted me about three years ago, and, after peptone treatment, got much better—in fact she remained clear for a long time, except for a little now and then. During the past two or three months she had asthma every night and was obliged to inject adrenaline frequently. I made serum peptone (20 per cent. peptone) and after four intravenous injections by Dr. Gardner of Sutton Valence she entirely lost her asthma.

It has been mentioned that peptone produces anaphylatoxin on incubating it with serum. But it also produces a great deal more, and it is worth considering how far the anaphylatoxin goes in treatment. When anaphylatoxin is injected into a guinea-pig it produces anti-anaphylatoxin, and if the blood of this animal is injected into another guinea-pig the latter becomes immediately resistant to a dose of anaphylatoxin (Dale and Kellaway\*). Now in the human subject an allergy differs greatly from an artificially produced sensitization, and it would seem from the minute doses of peptone often required that something else happens, which we are ignorant of, and which lasts a long time.

In man, the injection of 2 to 3 c.cm. of serum peptone does not as a rule produce reaction. Man resembles the dog in his anaphylactic reactions (Dean\*), and according to Dale† the dog is not affected by a dose of its own anaphylatoxin. But the guinea-pig and other animals readily show effects from anaphylatoxin of man.\* Anaphylatoxin does not appear if the mixture be heated to a point which destroys complement, whence it would seem that complement is necessary, but this has been doubted. The whole subject requires investigation. But the treatment is independent of this.

 \* In some samples of serum and serum peptone sent to Dr. Teale of University College he found that in the guinea-pig 2 and 3 c.cm. of the serum were without any effect; but the dose of serum peptone (15 per cent. peptone) killed the animals, after one hour with a 2 c.cm. dose, and in ten minutes after a 3 c.cm. dose, preceded by jerks.

## MENTAL SYMPTOMS IN AURICULAR FLUTTER.

BY

W. S. DAWSON, M.D. OXON., M.R.C.P. LOND.

THE following case is of interest from the point of view of the relation between the mental symptoms and the physical state.

A business man of middle age had for years lived a "high-pressure" life, had smoked heavily, and had been a steady drinker. A friend stated that for some weeks he had had occasional "heart" attacks and had complained of giddiness when crossing roads. On one occasion he had collapsed on climbing some stairs and was taken to a hospital, where he was detained for a few hours before being sent home. He had then stayed in bed for three weeks. Two days before he came under observation he had attempted to resume his work, but returned home early and could not say where he had gone or what he had been doing. He appeared not to recognize his friends, and kept anxiously inquiring as to the state of his affairs.

When first seen he walked with difficulty and appeared to be extremely confused, replied to questions in monosyllables and was quite unable to give any account of his symptoms. His pulse was rapid but regular, about 140 a minute, and the cardiac dullness was a little increased. The pupils were not quite equal and reacted a little sluggishly to light, but the consensual reflex and the reaction on convergence were normal. There were no l. bial, lingual, or digital tremors, and the tendon and cutaneous reflexes were normal.

On the following day he was perfectly clear and well orientated and could give a good account of himself except for the period of the five preceding days, which seemed to him to be almost a blank but for a great fear that he was about to die. He stated that he had been subject to fainting attacks for about a year, and that he had been ordered to lead a quiet abstemious life and to restrict his diet. He had lost weight in consequence and had felt much better in health, while the fainting attacks had become less frequent and less severe. Latterly, however, he had felt faint even when confined to bed. Tincture of digitalis was now prescribed, but appeared to have little effect, as the pulse rate continued to vary between 130 and 160. He remained clear in mind, but was often anxious and worried and had bad dreams at night.

I am indebted to Dr. C. F. T. East for the reports on the electro-cardiograms. The first report was as follows:

"The case is one of auricular flutter. The auricular rate is 360 and the ventricular 180 a minute. There is therefore 2:1 heart block. There is preponderating hypertrophy of the left ventricle."

The patient was now given Nativelle's digitalin subcutaneously in doses of 1/600 grain thrice daily. He improved considerably and became much less restless, but continued to feel faint at times. The pulse rate was still high and became irregular. The report on the electro-cardiogram was:

"The rhythm is now irregular and the intervals between the ventricular complexes are quite dissimilar. There is variation in the ventricular complexes. The regular sequence of P waves is not seen in this graph as was the case before. Instead there are a number of coarse deflections occurring irregularly. In some cases there is still somewhat of a resemblance to flutter in the P waves. The condition is now one of coarse fibrillation of the auricles somewhat transitional in type between true flutter and complete fibrillation. Preponderating hypertrophy of the left ventricle is well marked. This change may be the result of digitalis medication."

The injections of digitalin were now omitted and the pulse fell from 120 to 72. The next electro-cardiogram showed

"regular rate of about 72 a minute with very slight sinus arrhythmia. There is no delay in the conduction of impulses. Normal rhythm has now been restored and the impulse arises normally and pursues a normal course. The only abnormal feature is the preponderating hypertrophy of the left ventricle."

The patient appeared to be restored to complete health.

The pupils reacted normally in all respects, and mentally he was alert and clear and had lost his feelings of anxiety. There was a history of syphilis thirty years ago and his blood was found to give a +40 Wassermann reaction. It was not anticipated, however, that the cerebro-spinal fluid would show a similar reaction with a large excess of cells and protein. The patient was given a course of 16 grams of tryparsamide, but the blood remained +40 while the cerebro-spinal fluid was +20 with 15 cells per cubic millimetre, 50 mg. of protein per cent., and a paretic Lange reaction of 5555543210. The patient has been at work for several months, and when seen recently did not show any physical signs beyond slight enlargement of the left ventricle.

Although dizziness and complete loss of consciousness are not uncommon features in auricular flutter, mental confusion of several days' duration is unusual. The mental picture of this case was extremely suggestive of general paralysis, except that the symptoms disappeared as the condition of the heart improved. Visceral hallucinations such as have been described by Head were absent.

Intensive treatment with digitalin caused the vicious circle to be broken and converted the flutter into fibrillation, which in turn was followed by a normal rhythm when the drug was discontinued.

## PANNICULITIS: ITS SIGNS AND TREATMENT.

BY

WILLIAM BAIN, M.D., F.R.C.P.

HARROGATE.

PANNICULITIS can be correctly defined as a chronic interstitial inflammation of the fibrous tissue, the peripheral nerves, and blood vessels in the panniculus adiposus. Stockman<sup>1</sup> prefers the somewhat lengthy term "chronic subcutaneous fibrosis," but Professor Salin<sup>2</sup> had previously denominated the affection panniculitis, and most probably this concise term will be permanently adopted. The condition is quite common, and is not infrequently associated with fibrosis; indeed, it may be regarded as a superficial form of fibrositis, although it can be easily distinguished from the latter affection.

Unquestionably infection plays a part in the causation of some cases. There is generally a history of gastro-intestinal disturbance for months or years, which I regard as the predisposing cause in the majority of cases, and the exciting cause is usually a series of slight chills—not severe enough to confine the patient to bed. Although this affection occurs frequently in patients with neurotic symptoms, the question arises whether the panniculitis is not the cause of the neurosis. In a certain number of cases there are no symptoms referable to the nervous system. This fact must be emphasized, because the opinion is held that panniculitis is always associated with symptoms of neurosis.

There is a good deal of confusion regarding the signs of this affection. The description of the physical signs given by some writers is misleading. For example, one observer<sup>3</sup> describes hard nodular masses varying in size from a bean to a walnut; another<sup>4</sup> mentions that nodules were found running down among the branches of the brachial plexus; and a third<sup>5</sup> states that patchy areas of panniculitis give rise to thickening, and even tumours of a fibre-fatty nature. A nodule means a knot, knob, or lump. If this be the accepted meaning of the term, I have not met with a nodule in any case of uncomplicated panniculitis, and I have seen 85 cases during the last two years. Although it probably consists of pannicular deposits among the masses of subcutaneous fat, I exclude Dercum's disease from consideration, chiefly because it is not common, and the treatment of adiposis dolorosa is somewhat different from that of simple panniculitis.

Panniculitis occurs in small circumscribed patches, from about one to two inches in diameter. The seats of election are the supramammary regions in the female, the upper intercostal muscles (the left side being most frequently

affected, and, if both sides are attacked, the left is generally the worse), the costal margins, the abdomen, and over the fascia lata. Very occasionally patches may be found in other localities, but, apart from the fascia lata, as a rule they are confined to the trunk. Stockman's description of the microscopical appearance is as follows:

"The fibrous tissue is found to be thicker and denser than normal with numerous fibroblasts; the small nerve twigs running through it are in a condition of interstitial inflammation, and the small blood vessels show periarteritis and endoarteritis."

These observations upon the morbid histology of a patch established panniculitis as a distinct entity and explain the character of the physical signs. There is not much to be felt. The sensitive areas are generally smooth; when they are uneven they give the impression of a conglomeration of small shot-like particles. If pressure is applied perpendicularly to the surface the tenderness is slight, but if applied from the circumference of the patch it is most marked. A patch is evidently an aggregation of smaller ones. When the patch is disappearing under massage it splits up into its component parts. The contour of these can be made out, and before they finally disappear they feel like small pin-heads. On picking up the skin and subcutaneous tissue over a patch between the fingers, it feels firmer and less elastic than normal tissues. If the sensitive area is compared with a healthy portion, the practitioner will soon acquire the tactile discrimination necessary to diagnose this affection.

The implication of the nerves produces the symptoms, which are aching pain in the affected part, tingling, stiffness after exertion, numbness, muscular lassitude, and often a distinct loss of energy. Sometimes in early cases the patient is not conscious of any discomfort until the patch (or patches) is manipulated during an examination. The characteristic sign is the exquisite tenderness on picking up the sensitive part between the fingers.

Errors of diagnosis are not uncommon: for example, a case of left intercostal panniculitis was mistaken for angina; a patch over the right costal margin for cholecystitis, and another over McBurney's point for appendicitis. It is comparatively easy to distinguish between a hyperaesthetic skin area and a patch of panniculitis. In the former a slight stroking of the skin produces tenderness; whereas in the latter lateral pressure causes more or less severe pain.

#### TREATMENT.

The first essential is to improve the digestion. Over-eating or dietetic errors are usually the cause of alimentary irregularity. Secondly, to impress upon the patient the advisability of guarding against chill. If there is any septic focus it should be immediately dealt with. The fundamental principle of removing the cause, if possible, applies with special force to panniculitis. If the pain is severe, or interferes with sleep, a cachet consisting of magist, pyramidon, and caffeine citrate may be given occasionally; otherwise drug treatment, apart from a digestive aid, is of doubtful value. The best treatment for this affection is skilled massage, given preferably by one who has obtained the Swedish diploma. I generally begin treatment with mild electric massage (d'Arsonval) and then go on to dry massage. In very sensitive ladies the masseuse uses a cream consisting of menthol, methyl salicyl, and cremer rosae. It takes a few weeks before the patches completely disappear. About once or twice a week it is sometimes advisable to substitute for dry massage a massage douche to improve the general health. Dry massage may become somewhat irksome, and a douche is always pleasurable. The vacuum tube (d'Arsonval) has a soothing effect upon the tender area, but the remedy to promote absorption of the effused inflammatory products is massage skilfully given—at first tentatively, and as the tenderness diminishes more vigorously.

## CONGENITAL MEGACOLON WITH ABSENCE OF VAGINA.

BY

HAROLD HARTLEY, M.D.LOND., F.R.C.S.ENG.,  
SURGEON, NORTH STAFFORDSHIRE INFIRMARY.

EXTREME constipation and distension of the abdomen present at birth as in the following case without organic obstruction, but with hypertrophied, dilated, and elongated sigmoid colon, are typical of the condition first adequately described by Hirschsprung.

M., a girl now aged 18, the second of eight children, was the only one born with abnormalities. The mother ascribes the daughter's defects to conception having occurred at a time of great distress caused by her first daughter's death from meningitis.

M. suffered from extreme constipation from birth—the midwife had to use aperients and enemata to get away the first motion, which was sepyulous, and a doctor had to be consulted. The abdomen became greatly distended. When 5 years old colostomy—in the mid-line below the umbilicus—was performed by another surgeon, and then, for six years, injections had to be used three or four times a week and the bowels were only opened naturally per anum about once in three months. The mother says she could not afford a colostomy apparatus and by the time her daughter was 11 years old begged for something to be done.

On August 10th, 1917, I excised the faecal fistula with an enormously hypertrophied and dilated sigmoid colon. End-to-end anastomosis was done, and a tube passed through the anastomosis and stitched to the anus (Lane's technique). The large bowel not removed seemed almost normal in size but to have thick walls. Since then the bowels have acted naturally; the abdomen is not distended; there is no incisional hernia. The girl earns her living as a shop assistant.

Since she reached the age of 16 there have been mild attacks of abdominal discomfort, sometimes with vomiting, about every three weeks, but as menstruation did not appear she again came under my charge. No trace of vagina or of uterus could be found, even after deep incision into the perineum. The urethra is normal; the rectum roomy and unobstructed, and the secondary sexual characters, though backward, are definitely feminine. If she insists on getting married at some future date it is proposed to fashion from a segment of the ileum a substitute for the missing vagina (Baldwin's operation).

In the textbooks cases like this are not sufficiently separated from those with organic obstruction—for example, of 100 cases collected by Mummery organic obstruction was found in 23. The same authority says: "Curiously enough associated congenital abnormalities are apparently not common." Of his 100 mixed cases, only 15 presented some other congenital abnormality—in 10 abnormality of the anus; in 2 stricture of the colon; in 2 deaf-mutism; in 1 imbecility. Such abnormalities are nothing like so striking as those here recorded.

In another condition where hypertrophy of muscle is present at birth—congenital hypertrophic pyloric stenosis—there is also but rarely found an association with other congenital abnormalities (for example, club-foot). These two conditions—apparently closely comparable—were both first properly described by Hirschsprung. It seems idle to guess why, how, or when such defects arise. At any rate, we can summarily dismiss many of the hypotheses put forward to explain congenital megacolon, because they fail to take into account such facts as the absence of organic obstruction, the presence sometimes at birth of distension of the abdomen, as well as hypertrophy and dilatation of the colon, and the not rare extension of the dilatation right down to the anal canal, and because they do not throw the origin back far enough.

Probably at the present time the help of the sympathetic nervous system would be invoked: a "sympathetic block" might account for achalasia or for a zone of reversed peristalsis or of want of peristalsis, but it is very doubtful whether any neuro-muscular defect could produce hypertrophy even if it caused spasm. We can produce deformed starfish at will by shaking, needling, or otherwise interfering with the segmenting ovum. So in attempting to explain congenital deformities in the human species we can go right back to the egg stage—some "impression" on the ovum might result in an abnormal trophic control (nervous or chemical), with the result of overformation of muscle. At any rate, in the present case the mother was on safer ground than is usual in placing her "maternal impression" at the time of conception.

Even as regards the treatment of megacolon, there is much difference of opinion. In the case here related treatment was of necessity surgical: colectomy was demanded, and the result surpassed expectation.

Colostomy may be done as a first stage, but should, if possible, be followed by excision of the artificial anus with colectomy and anastomosis. Mummery advises the lumbar route for colostomy, saying that inguinal colostomy is very dangerous, as the heavy bowel tends to tear away, that a spur cannot be formed, and the obstruction is often not relieved, and that he has only found two cases in which any real benefit resulted.

Colectomy, no doubt, is a very formidable undertaking in a toxic, undernourished patient, especially in the presence of a faecal fistula; but most people would prefer to take the risk to passing adolescence and maturity in the alternative condition.

## TREATMENT OF GENERAL PARALYSIS BY MALARIA.

BY

T. WISHART DAVIDSON, M.B., CH.B.GLASC.,  
D.P.M.MANCH.,

SENIOR ASSISTANT MEDICAL OFFICER, WINWICK MENTAL HOSPITAL.

DURING the past two years (from November, 1922, to November, 1924) 608 acute male cases have been admitted to this hospital. Most of the patients giving a history of syphilis, or showing signs and symptoms, definite or suggestive of a late specific infection, have been subjected to the diagnostic biochemical tests. The Wassermann and Sachs-Georgi tests have been applied to the blood and cerebro-spinal fluid, and the colloidal gold test to the latter. Of the two years' admissions, 89 (14.6 per cent.) have been diagnosed as suffering from general paralysis. This percentage may later prove to be greater, as many patients recently admitted have not yet been subjected to the various tests.

The youngest patient (acquired infection) was aged 27, the oldest 61. The duration of the attack before admission, as shown by change of conduct, varied from seven days to five years. As a cause of death general paralysis accounted for 44 out of 95 deaths in the two years—that is, 46.3 per cent., a remarkably high figure.

In November, 1923, the malarial treatment of general paralysis was commenced. Professor W. Yorke of the Liverpool School of Tropical Medicine kindly provided the mosquitos (*Anopheles maculipennis*) infected with an Indian strain of *Plasmodium vivax*. During the year 53 cases were treated. The infection was conveyed by the mosquito in 23 cases; by inoculation in 30 (intravenous 16, intramuscular 13, subcutaneous 1). The incubation period, measured by the appearance of parasites in the peripheral blood and the occurrence of fever, varied according to the mode of infection, thus:

	Average.	Shortest.	Longest.
Mosquito ... ..	14 days	7 days	20 days
Intravenous ... ..	7 "	4 "	19 "
Intramuscular ... ..	16 "	10 "	23 "
Subcutaneous ... ..	20 "	—	—

In two cases the incubation period following intravenous inoculation was four days.

(a) April 14th, 1924: Inoculation of 2 c.cm. of blood from donor during apyrexial period after six double tertian rigors. Pyrexia of 102° F. on afternoon of 17th; blood positive on April 18th.

(b) May 28th, 1924: Inoculation of 2 c.cm. of blood from donor after three single tertian rigors. Pyrexia of 101° F. on night of May 31st; blood positive on June 1st.

The infected patients were allowed to have rigors; ten was the number aimed at, but in thirty instances, owing to the poor general state of the patient, the malaria was cut short with quinine sulphate somewhat sooner. Thirty grains daily for three days were always given. Seven rigors was an average number. Spontaneous cure with disappear-

ance of the parasites occurred in 8 of the remaining 23 cases (34.7 per cent.) after three to nine rigors. This percentage would probably have been greater had the malaria been allowed to run a longer course in some of the other cases.

It is generally considered that large doses of the arsenical compounds are contraindicated in cerebro-spinal syphilis. Doses of 0.15 to 0.3 gram novarsenobillon were given at first; this dosage was increased, and finally 0.9 gram was given intravenously at the height of the pyrexia. Seven cases were treated with this maximum dose and no ill effects were observed. The parasites became scanty within two days, but quinine in the usual dosage was finally given to clear the blood.

When remission in the general paralysis occurred it took place at any time; in some during the period of malarial pyrexia and in others as long as six months later.

### Results of the 53 Cases Treated.

1. Complete remission ... ..	7=13.2%
2. Improving both mentally and physically ...	9=16.5%
3. Slight mental with improved physical health ...	17=32.0%
4. No change mentally or physically ... ..	5=9.4%
5. Deaths from time of treatment up to one year after, including 6 who collapsed ...	15=28.3%

In Class 3 seven of the patients were bedridden, dull and confused, and wet and dirty in their habits; following treatment the mental condition improved slightly, but the physical change was marked. The patients put on weight, regained control of the sphincters, and were soon able to be up and about in the ward. Two patients have been in this state of partial remission for twelve months.

Relapses of the malaria have been frequent (14 up to date). Of the original 23 mosquito infections, 13 (56.5 per cent.) have relapsed, whereas of the 30 inoculated cases only one (3.3 per cent.) has relapsed. The relapses in the mosquito-infected cases have occurred at periods varying from twenty-one days to eleven months after. The usual three-day course of quinine was given, but in a number of instances two, and even three and four, further pyrexial attacks were observed.

Wagner-Jauregg,<sup>1</sup> Mühlens,<sup>2</sup> Kirschbaum,<sup>3</sup> and Grant and Silverston<sup>4</sup> have already pointed out the infrequency of relapse in inoculated cases of malaria. The high percentage of relapses in the mosquito-infected cases is similar to the percentage of relapses in the naturally infected cases of the late war—38 to 100 per cent. of relapses following courses of quinine (Yorke and Macfie<sup>5</sup>). It would appear that passage through the mosquito in some way produces an infection which is more difficult to cure than the inoculated disease, though the two infections would appear to be identical as regards the type and severity of the pyrexia and the blood picture. Following the hypothesis of Yorke and Macfie, the mosquito strain, whilst reacting to quinine, in many instances soon becomes resistant to the immune body; some parasites persist, though not found in the peripheral blood, there being a state of balance. Sooner or later the balance is lost by decrease or weakening of the immune body; the parasites multiply and relapse occurs, with or without a rise of temperature according to the reaction of the host. On the other hand, the inoculation strain responds to quinine, and would appear to be completely destroyed by the immune body formed. The question still remains, however, why patients infected by the mosquito relapse so frequently as compared with those inoculated under the same conditions. In these experimental cases it would appear that the mosquito strain is more resistant, rather than that there is variation in the capacity of the host to produce immune body.

Infection followed feeding by mosquitos, or the injection of malarial blood, in all cases treated, but in two instances there was no pyrexial attack, simply the appearance of parasites in the blood. Blood infection only, without pyrexia, occurred also in a third patient who already had had an attack of inoculated malaria. The circumstances are of interest.

### CASE I.

The patient had been treated with malaria in a general hospital four months previous to admission to the Mental Hospital. He had had eight to ten rigors, followed by spontaneous cure, but parasites persisted in the peripheral blood. On January 7th, 1923, when malaria treatment was considered, the blood was found to be positive. Quinine sulphate, 10 grains daily, was given

from February 15th to 23th. Infected mosquitoes were fed on February 20th, and thus 60 grains were given before the infection and 90 grains after. No pyrexia followed, but the blood showed scanty parasites from March 14th for a few days, thereafter becoming negative. On April 23rd parasites again found. From April 23rd to 25th quinine sulphate, 30 grains daily, was given. On May 24th an intramuscular injection of 2 c.cm. of infected blood was given, but no infection followed, the blood remaining negative.

## CASE II.

The patient gave a history of malaria previously. On August 23rd, 1924, an intramuscular injection of 2 c.cm. of infected blood was given. No pyrexia followed, but the blood became scantily positive from September 2nd to 6th; thereafter it was negative. On September 16th the patient was again inoculated intramuscularly with 2 c.cm. of infected blood. The blood became positive from September 20th to 27th, but there was no temperature. On December 7th, 9th, 12th, and 15th intramuscular injections of 1 c.cm. of adrenalin were given; and on December 10th 1 c.cm. of milk. The blood continued to be negative until December 15th, when two infected cells were found in the blood film.

## CASE III.

The patient was infected with mosquitoes on November 23rd, 1923; double tertian infection followed; he was allowed to have twelve rigors. Quinine sulphate, 30 grains daily, was given from December 23rd to 25th. As there had been little mental change an attempt was made to reinfect on July 20th by intramuscular injection; no temperature followed, but the blood was positive from August 1st to 4th; after that it was negative. Even here, however, the parasites appear to have become resistant to the immune body, for there was relapse with parasites in the blood from August 24th to 30th, but no temperature.

## SUMMARY.

1. The malaria treatment of general paralysis is justifiable and hopeful, provided the patients are in fair physical health. The earlier the case the better the prognosis. The treatment is contraindicated where the patient is likely to have a fatty heart or where there is poor physical health. It may be added that the administration of strychnine, with digitalin or strophanthin to steady the heart, is advisable and helpful, especially during the later pyrexial attacks.

2. Relapses of malaria do occur, but practically only in mosquito-infected cases.

3. Compared with infection by the inoculation of trophozoites, it would appear that infection by the sporozoites from the mosquito produces a parasite which readily becomes resistant to the immune body, and thus relapses frequently occur.

4. A previous attack of malaria would appear to induce partial immunity; although scanty parasites appear in the peripheral blood, there is no rise of temperature.

I wish to thank Professor Warrington Yorks for providing the infected mosquitoes and for his encouraging advice; Dr. G. A. Watson, pathologist to Rainhill Mental Hospital, for assistance with the biochemical tests; and Dr. F. M. Rodgers, medical superintendent of Winwick Mental Hospital, for permission to publish these notes, and for his kindly supervision and guidance.

## CONGENITAL NYSTAGMUS.

BY

T. STENNER EVANS, M.B., B.S.LOND., D.P.H.,  
FOCHIRW, GLAMORGAN.

The occurrence of congenital nystagmus is sufficiently uncommon to justify the record of a series of cases in a single family in which the condition appears to be hereditary.

A woman, aged 55 years, recently consulted me about her eyesight. She had marked nystagmus of the lateral movement type, without rotary movements of the eyeballs or spasm of the eyelids. Her optic discs were pale, but beyond a moderate degree of presbyopia there was no visual defect. The woman volunteered the information that her father and grandmother (both of whom she remembered well) had always suffered from a similar condition. The patient had six children—five daughters and one son. Of these children, the son suffered from marked nystagmus, but with the exception of one of the daughters (who suffered from slight nystagmus) the female children showed no trace of the condition. The son married recently, and his young

daughter has nystagmus. Hence it can be seen that in five generations of this family nystagmus makes its appearance, and is transmitted through both male and female members of the family. I cannot recall any instance of an abnormal condition transmitted so definitely both by male and female. In haemophilia, and in the muscular dystrophies, transmission of these diseases is through the female to the male, the female very rarely suffering from the condition.

Some points of general practical interest also arise in this connexion. Some time ago a coal-miner suffering from nystagmus endeavoured to establish a claim for compensation on the ground that his nystagmus was due to his occupation. It was subsequently discovered, however, that at an early age the patient had been seen by the surgeon who was now examining him for compensation. The surgeon's notes showed that the patient had suffered from nystagmus, which had manifested itself at an early age, before he entered a coal-mine. Hence the claim for compensation failed.

During the recruiting days of 1916 one of the male members of the family whose history I have outlined was called up by the army authorities for examination as to his fitness for service. The examiner noticed that the man had nystagmus, so in view of the man's statement that he was a coal-miner he told him that he was unfit for service. A careful examination, however, would easily have excluded miner's nystagmus, for apart from the movements of the eyeballs and slight nodding spasm there were no other signs to justify this diagnosis.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## GREEN TEETH FOLLOWING PROLONGED JAUNDICE IN INFANCY.

The occurrence of green teeth following jaundice in infancy is so rare that the following case is worth recording.

## History.

Caroline F. is now 2 years and 4 months old. She was born at full term after a normal labour. The mother, now 39 years old, enjoyed good health during the pregnancy and had no illnesses or fevers of any kind; she has had no miscarriages. The father is 44 years old, and is well. There are three brothers (aged 24, 18, and 14), and three sisters (aged 20, 8, and 4), alive and well; none of these children showed jaundice at any time. One sister (the third child) died when a week old; it suffered from imperforate anus, which apparently could not be relieved; it was not jaundiced. There is nothing else noteworthy in the family history.

C. F. was born jaundiced—"as yellow as a duck's foot" the mother said; the skin of the whole body and limbs was coloured yellow, and so were the sclerotics. The jaundice continued to be intense and quite constant for three months, then it became gradually less, but it had not entirely disappeared until the child was 7 months old. All this time the child was "fairly well in itself." The motions (two or three a day) were green, loose, and slimy for six months. The child for six months was given a grey powder each day. All that the mother can tell about the urine is that it stained the clothes a deep yellow for several months. The umbilical area was "septic" for three weeks after separation of the cord. At birth the child weighed 5½ lb., and it regularly increased in weight, so that at 8 weeks it weighed 8½ lb., at 24 weeks 13 lb., and at 1 year 21 lb. It was never at the breast, but was fed on cow's milk (diluted suitably) until it was 9 months old, and thereafter there were the usual additions to its dietary.

With the exception of the prolonged jaundice and "a slight bronchitis every time she cut a tooth," the child has had no illnesses of any kind. The first tooth, a lower incisor, was cut at 9 months, and teeth appeared regularly after that in this order: lower central incisors, lower lateral incisors, upper central incisors, upper lateral incisors, first molars, then, at 2 years, the lower canines, and lastly the upper canines (not yet fully erupted). The first tooth "came in green," and all the others have done the same.

## Condition on Examination.

The child is well developed and well nourished, and weighs 28 lb. There is some rickety thickening of the bones about the wrists and ankles; otherwise the chest and limbs are well formed. Nothing abnormal was found on examination of lungs, heart, nervous system, or abdomen. The spleen is not palpable. The liver edge can just be felt at the costal margin. The urine and stools are normal. No jaundice is now present. Mentally the child is normal. The Wassermann reaction is negative.

I am indebted to Dr. Crombie, dental surgeon to the hospital, for the following report on the teeth: "The temporary teeth are stained green, to the extent of the whole of the crown of the central incisors, about three-quarters

of the crown of the lateral incisors, a good tip of the cutting edge of the canines, and fully half of the crown of the first molars. The second molars are not erupted. I think the staining is confined to the dentine, as the enamel at the cutting edges of the incisors seems to be free of stain. Still, it is quite possible that there is some staining of the enamel, and it will be interesting to see if this is so, or not, when you get sections, some years hence, of a shed tooth. The staining approximates very closely to the amount of dentine that has been formed at the period just after birth."

Assistant Physician, Royal Aberdeen  
Hospital for Sick Children.

### NASAL DIPHTHERIA.

I HAVE recently been impressed by the large number of cases of nasal discharge which I have seen at the Birmingham Children's Hospital, in which nasal swabs have yielded the Klebs-Loeffler bacillus. These cases rarely exhibit general symptoms. The nasal discharge is usually bilateral, but in at least two cases it was unilateral.

There seems no particular characteristic whereby the disease can be recognized clinically. In no case have I noted a definite membrane on the nasal mucous membrane, though in two cases the nasal pus was coagulated, and in two others coagulated with blood. The other cases resembled chronic purulent rhinitis.

The importance of the condition seems to me to be twofold:

1. It is unwise to operate for tonsils and adenoids in ignorance of the nasal condition.
2. These cases are diphtheria carriers, and may be contributory to the prevalence of diphtheria at the present time.

Birmingham.

### SHOCK DOSES OF *B. COLI* VACCINE IN EXOPHTHALMIC GOITRE.

The following notes are founded upon eighteen cases of exophthalmic goitre treated with shock doses of *B. coli* vaccine. The dose was 500 million. No case required more than six injections, which were given every seven days. At first patients were kept in bed for four weeks. Later this proved unnecessary, except in severe cases. Every patient had the classic symptoms. The benefit from the vaccines persisted long after the cessation of the injections. In nearly every instance *B. coli* were found in the urine. Every case resulted in cure. The vaccine treatment of simple goitre, in my hands, proved to be less successful. Four cases of exophthalmic goitre and one of simple goitre in a dog call for comment.

Case 1.—A lady who had lost 4 st. in weight and had been in bed for ten weeks was (1913) given an injection; three or four days later the pulse had fallen from 160 to 100. Six injections sufficed for recovery. To-day she is in perfect health.

Case 2.—This patient, in addition to exophthalmic goitre, had bacilluria, pyuria, and an infected right kidney. Her first symptoms calling for medical advice were those of appendicitis. After fourteen weeks in bed convalescence was complete.

Case 3.—In this instance the vaccine always caused a local reaction in the thyroid gland.

Case 4.—This patient had been treated by several physicians by, among other remedies, x rays. Six injections removed all nervous symptoms, with a gain, in twelve months, of 2 st. in weight.

The object aimed at was to produce a slight and fleeting pyrexia. On one occasion a dose of 1,000 million produced pyrexia of 102° to 103° for three days. This served no useful purpose; 500 million proved both safe and satisfactory.

The following instance of simple goitre in a dog is not without interest.

A spaniel was brought to me with a thyroid enlarged to the size of a lemon, which was causing dyspnoea. After a first injection of 250 million the swelling was reduced in a fortnight to the size of a Tangerine orange. After a further injection of 500 million the tumour in another fortnight was the size of a walnut. No more injections were given, and in eight weeks from the start there was no sign of the swelling. A year later the dog remains in perfect health.

Such a result does not point to a specific effect of the vaccine; rather does it indicate an alteration of the metabolic balance, the difference between health and disease. The following case points to a specific effect.

A girl, aged 14, with endocarditis and pericarditis, had been given the usual remedies, and also rheumatic vaccine. No effect was produced on the pyrexia; the urine contained *B. coli*. She was given 250 million *coli* vaccine. In three days the temperature dropped to normal, though it rose again at the end of another four days to the old condition of 102° to 103.5°. After injection of 500 million the temperature fell to normal for seven days. Thereafter weekly injections prevented pyrexia and brought about gradual convalescence.

Formby, Lancs.

ARTHUR C. WILSON, M.B., CH.B.

### ACUTE CALCULOUS CHOLECYSTITIS AND MALIGNANT DISEASE.

As the carcinomatous condition in the following case was not apparent at the time of operation, it lends support to the opinion that cholecystectomy is the operation of choice for cholecystitis rather than drainage of the gall bladder; had the gall bladder not been excised the malignant condition would not have been detected.

A married woman, aged 60, was admitted to hospital on January 13th suffering from acute epigastric pain and vomiting. Both recti were rigid, particularly the upper half of the right, and the whole abdomen was tender. The maximum tenderness was over the gall bladder. Acute cholecystitis was diagnosed and laparotomy decided upon.

The gall bladder was explored through an incision splitting the upper fibres of the right rectus. She had suffered from previous attacks of a similar but milder nature, and this was apparent during the operation by the numerous adhesions around the gall bladder. When exposed the latter was found to be acutely inflamed, but small and very hard. The liver appeared normal. Cholecystectomy was performed, working from the fundus towards the cystic duct. The fossa was drained for forty-eight hours. She made an uninterrupted convalescence, and was discharged from hospital within three weeks of her admission.

Examination of the gall bladder after removal showed that it was neatly inflamed and contracted upon its contents, five mulberry-shaped calculi. These were not faceted, were about the size of peas, and mottled brown and white. In addition to the calculi, and lying near the fundus of the gall bladder, was a hard patch which cut like an unripe pear. This was thought to be carcinomatous, and histological investigation verified this assumption.

I am indebted to Dr. J. T. Bailey for permission to record this case, also to Dr. Norman Kletz, pathologist to this hospital, and to Dr. David Greig, conservator of the museum of the Royal College of Surgeons of Edinburgh, for kindly reporting on sections made of the hard area. Their reports agree that the hard area is a carcinoma.

This case appears to be of interest, in the first place, because it affords another instance of the association of gall stones with cancer of the gall bladder; secondly, because such an association, although undetected at the time of the operation, amply justified the performance of cholecystectomy; and thirdly, because the possibility of such association adds to the mass of evidence in support of cholecystectomy, as opposed to cholecystostomy, in the treatment of acute cholecystitis.

Stockport Infirmary.

LAMBERT ROGERS, F.R.C.S. Edin.

### A CASE OF TRUE EPISPADIAS.

A boy, aged 15, was sent to me by Dr. Hornsby of Greenock. The patient's general development, both physical and mental, was rather below par. The penis was little more than an inch in length, but, except for the deformity and absence of the prepuce, was otherwise well developed and of fully normal diameter. The glans was well formed, and the ventral median raphe clearly defined, as it appears after circumcision. Thus there could be no question as to which was the dorsal and which the ventral aspect of the penis, and it was therefore clear that the penis was not twisted, and that the cleft was definitely on the dorsal aspect, from which it extended downwards, between the corpora cavernosa, to the position of the urethra. The cleft was deep and narrow, and ran from the normal urethral orifice, backwards through the dorsal aspect of the glans, to near the root of the body of the penis.

A simple flap operation was easily performed, and was entirely successful in removing the deformity and in forming the urethra.

JOHN A. C. MACGOWEN,  
Surgeon, Royal Infirmary, Glasgow.

## Reports of Societies.

### DRUGS AND SOLUTIONS USED IN LOCAL ANAESTHESIA.

At a largely attended meeting of the Section of Odontology of the Royal Society of Medicine on February 23rd, Mr. J. G. TURNER presiding, a report was given by Mr. F. N. DOUBLEDAY on some experimental work which he had undertaken, with the help of others, on the drugs and solutions used in local anaesthesia.

Mr. Doubleday explained that his purpose had been, in the first place, to secure evidence with regard to the chemical structure and reactions of certain of the drugs so as to lay a more certain foundation of knowledge regarding their use and to enable dental surgeons and others to estimate more effectually the probable value of new drugs offered for their use. A second object of the experiments, which had extended over a year, had been to offer evidence as to the causation of minor discomforts, such as stiffness, swelling, and after-pain, which were, in his experience, the only ill effects following the use of local anaesthetics for dental and minor surgical operations. In the chemical part of the work he had been greatly assisted by his colleague Professor Gibson, of the chemistry department of Guy's, who had drawn out for him tables (which he exhibited) of the graphic structure of some of the local anaesthetic drugs which had been used; these included novocain, stovaine, alypin, atropine, and others. With regard to tests, Mr. Doubleday considered that the tables given in the second volume of Martindale's *Pharmacopocia* were the best extant, but they were not absolute for all. There was no absolute test for novocain and other local anaesthetic drugs, and that was a serious drawback. He had hoped to have been able to dialyse solutions of novocain against other drugs and examine the filtrate, but that was prevented by the absence of absolute tests.

Some important experiments were carried out on the question of temperature and evaporation. A local anaesthetic solution was boiled, in the same way as for patients, and the solution was loaded into a syringe which had been previously boiled and allowed to become absolutely cold. A thermometer was kept in a tumbler of water at boiling point in order that the initial temperature of the thermometer should not in itself be a cause of alteration of temperature to the fluid in the barrel of the syringe. By using a cold syringe and a hot solution in that way the result was, as shown by a number of tests, within a degree of the body temperature. If the fluid in the containing mugs supplied for the purpose were allowed to boil furiously for one minute, or even for half a minute, at the end of that time only 2.5 c.cm. remained instead of the 3 c.cm. intended, so that the injection of this solution, which originally was approximately isotonic with the fluids of the body, became unduly concentrated, resulting in the swelling, after-pain, and stiffness of which patients complained. The same was true of test tubes. Long test tubes were best because any fluid evaporated recondensed on the upper part, and found its way back to the bottom again. Another point was the reaction of the glass itself upon the fluids. If the glass contained much soda then its effect upon the degree of alkalinity of the solution was quite definite.

Experimental work previously carried out had been along the lines of injection into the blood stream or into the heart. The effect produced by injecting into the blood stream was different from that produced by injecting into the connective tissue. Some might think that the material injected travelled along the course of the nerve until it came to the cells of the central nervous system; it was necessary, however, that the drug should come directly into contact with the protoplasm of the axis-cylinder process, and so inhibit its activity. Mandibular sensations—in their control experiments on man he and his co-workers had carried out many mandibular injections upon themselves—were definite under local anaesthesia: there was first tingling of the lips, and after five, seven, or ten minutes the tactile sensation of the periodontal tissue was

"doughy"; the sensation of the pulp was the last to go. If, on one attempting to extract a tooth, the patient protested, an interval of ten minutes would enable one to extract it without protest. Sensation was restored in the inverse order to that in which it was lost, and this depended on the rate of diffusion of the local anaesthetic and on its linkage with the axis-cylinder process.

When considering the effects upon human beings, one came upon the complicated psychological problem, including the influence of the operator on the patient, the degree of alarm felt by the patient as to what was going to be done to him, and so forth, so that one could not get a standard. That was one of the reasons why frogs were chosen for experiment. It was necessary to avoid injecting towards the spinal cord, for if that were done the whole sacral nerves would be paralysed and double hemiplegia result. On using  $\frac{1}{2}$  per cent. solution of novocain and adrenaline, it was found that the frog recovered from a 5-minim dose in from one to one and a half hours, and that was comparable with the recovery period of the human being. The dosage for the frog in proportion to the human was very heavy. The experiments showed that merely exposing the frog's heart or injecting the saline did not interfere with its action. With novocain and adrenaline 2 minims produced slight alteration in the heart, 3 minims showed a slowing of the ventricular contractions; with 5 minims the auricular contraction began to fail, and fifteen minutes later there was a great inhibition of the heart, and that became progressive.

His conclusion was that adrenaline and novocain produced a definite depressive action on the heart. Novocain alone caused the heart to drop a beat or two, but did not seriously affect it. Adrenaline alone, 1:20,000, produced a progressive slowing of the heart with failure of its auricular contractions. He had tried to find a more suitable drug to combine with adrenaline so as to minimize the effects of the latter. Caffeine failed to prevent the depressive action of the other drugs. Strychnine had been widely recommended as a supposed antidote to novocain and adrenaline, but it was powerless to stop failure of the heart. Trials of 5-minim injections of novocain and adrenaline with atropine resulted in the heart contracting vigorously. He was of opinion, therefore, that atropine was the best drug to combine with novocain and adrenaline to prevent the effects of adrenaline poisoning. The disadvantage of atropine was the resulting dryness of the mouth.

Mr. Doubleday showed a number of blood films which were taken after the use of local anaesthetics, and he proceeded to demonstrate that the best effect of local anaesthetics could not be obtained unless the injection was into connective tissue and muscle. He also showed sections of the kidneys of the experimental frogs, and the lecture was illustrated by a very large number of graphs and other exhibits.

#### Discussion.

Mr. F. ST. J. STEADMAN expressed his admiration for the paper, and said that this kind of research was very much needed if the odontologist was to be sure of his facts. He had long been convinced that adrenaline had a definite action on the human heart. If  $\frac{1}{400}$  grain of adrenaline was given to a patient there was nearly always complaint of throbbing in the head and general illness. This was prevented by giving a smaller dose. He strongly supported what Mr. Doubleday had said about the effect of the composition of the glass: he had confirmed this by powdering glass and adding to it sulphuric acid. He was convinced also that there was a personal idiosyncrasy in the matter of these drugs.

Dr. A. LIVINGSTON considered that the frog was not an ideal animal upon which to base conclusions for the human subject; in the case of the smaller animals the time factor was so very much shorter. The time of general anaesthesia for a frog should be one-sixteenth that of the human subject. He also asked whether Mr. Doubleday was sure that the experiments were carried out under exactly the same conditions with regard to temperature, draught, moisture, and other physical conditions. It was clear that the danger drug was adrenaline.

Mr. COLIN KEAY asked whether Mr. Doubleday had found any relation in the results obtained when using potassium

sulphate instead of Ringer's solution. Before the war two Germans suggested the use of 0.5 per cent. of sodium chloride and 0.4 per cent. of potassium sulphate, and claimed that this increased the potency of the novocain almost to that of cocaine.

Mr. DOUBLEDAY said that at a previous discussion in the society he had mentioned that he had only had three patients who were specially susceptible to novocain poisoning; he had since had the opportunity of proving absolutely, in two out of these three, that the danger arose from the adrenaline, not from the novocain. In the doses used by dentists, however, he did not think it constituted a harmful factor. In answer to Dr. Livingston, he thought that the frog, being a cold-blooded animal, readily adapted itself to the heat and other conditions of the ordinary investigating laboratory. With regard to the point raised by Mr. Keay, among the other things inquired into was the degree of alkalinity and acidity of the fluids used, and he got two colleagues, one in London and one in Cambridge, to work this out; independently they got the same result—namely, that the acidity of the solution was 7.68. One of them had suggested that acid sodium phosphate should be added to the solution to increase its isotonicity.

### PREVENTIVE CONTROL OF DIPHTHERIA.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on February 26th, the President, Dr. JOHN McVAIL, in the chair, Dr. WILLIAM ROBERTSON, M.O.H. Edinburgh, read a paper on the preventive control of diphtheria.

Dr. Robertson, having remarked that the usual measures with regard to diphtheria had somewhat the taint of locking the stable door after the steed was stolen, and referred to the anxiety given to all public health departments by the presence of carriers, described the methods adopted in Edinburgh to secure a systematic immunization of the school population. Explanatory leaflets and consent forms were distributed to all scholars under the age of 10 years. Parents were asked to consent to a preliminary Schick testing, then, if necessary, three preventive inoculations and a final Schick testing. In the better class schools as many as 86 per cent. of the parents consented, but in the poorer districts the percentage sometimes fell to 40; when the percentage of consents was 50 or less a second appeal sometimes brought the figure up to 70. When skilled workers were employed and the co-operation of teachers secured, it was possible to make the tests at the rate of 100 to 120 an hour. It was found, as elsewhere, that the proportion of positive reactors was much higher in the better social strata. It also appeared that passing through an attack of diphtheria did not confer a lasting immunity, as judged from the Schick reaction. Experience had shown that in young children, aged 2 to 5, immunization could properly be done without a preliminary Schick test. From the preventive point of view it would be expedient to concentrate attention upon children of pre-school age. It was essential that the method should be applied only by trained persons.

Sir WILLIAM HAMER wished to have more information as to the results, in particular with regard to the New York experience.

Dr. O'BRIEN remarked that the mixture used in Edinburgh was, so far as guinea-pigs were concerned, much less toxic than that employed in New York. He referred to improvements already effected in the production of antitoxin, and looked forward to yet greater improvements.

Dr. S. MOSKOTON COPEMAN remarked that in England, so far, only schools attended by the wealthier classes and Poor Law schools had made much use of the method. The higher percentage of immunes in the poorer classes was apparently due to more frequent normal exposure, because, in a higher grade school in Norfolk, where there was definite exposure to risk, the proportion of negative reactors had been found to be very large.

Sir GEORGE BRENNAN hoped that it would be possible to ascertain whether the subsequent attack rate of the immunized children in New York was lower than that of those

not immunized. He congratulated Dr. Robertson on this piece of work, and inquired whether reactions on inoculation had given rise to trouble, and whether it had been found necessary to warn parents.

Dr. MAJOR GREENWOOD deprecated any premature attempt to "prove" the efficacy of the process by statistics. At present the method should be regarded as a reasonable one—one to be accepted by intelligent people; in time a statistical assessment would be possible.

Dr. RANDALL asked whether immunization had reduced the number of carriers. Dr. TROTTER thought that the public health services in Scotland had a considerable advantage over those in England both by virtue of having somewhat greater powers and of being in closer contact with the people. Dr. HUMM thought that the small size of Edinburgh compared with London, and the prestige of its medical school, explained the greater willingness of the population to follow medical advice. Dr. SCOTT thought that the variation of the proportion of natural immunes was one of the most interesting problems from the standpoint of immunology; the explanation by subinfection was not really very satisfying. Dr. FOMMERS said that Edinburgh stood alone in dealing with the school population. In the South the method had been practically confined to large institutions. Dr. REGINALD DUNN remarked that, as in the matter of tuberculosis dispensaries, Edinburgh was doing pioneer work. He inquired as to the verification of a history of previous diphtheria, and also asked for information on the subject of carriers.

The President tendered his congratulations and those of the Section to Dr. Robertson. It was difficult not to be envious of New York. Probably the medical profession required more education, and he thought that Dr. Humm's remarks on the medical atmosphere of Edinburgh were highly relevant. He also deprecated any premature statistical "proofs."

Dr. ROBERTSON, in his reply, said that it was too early to give statistical results, but in a school which had formerly given much trouble no cases had occurred among the immunized. It had not been found necessary to issue warnings as to reactions. There were some reactions at the age of 10 to 11, but they were confined to slight rises of temperature and local induration. The method was not serviceable in the elimination of carriers: the carrier did not react. Histories of alleged diphtheria were verified from notification records.

### THE CONTROL OF TUBERCULOSIS AND THE MILK SUPPLY.

The general debate on this subject was resumed on Monday evening, March 2nd, when the chair was occupied by the President of the Section of Epidemiology, Dr. JOHN C. McVAIL. (For report of opening of discussion see *BRITISH MEDICAL JOURNAL*, February 14th, p. 309.)

Dr. M. J. ROWLANDS gave a description of the methods he employed on his farm to keep his cows and pigs in a high state of health, placing in the forefront the feeding by means of fresh vitamin-rich foods, and abandoning the artificial cake feeding so common. The latter he found to be absolutely deficient in vitamin A. He said it was not within Nature's scheme that cows should be continually supplying milk for human consumption; it was only intended that they should supply sufficient for their own progeny.

Dr. STANLEY GRIFFITH spoke from the bacteriological side, and exhibited tables showing the high proportion of bovine tuberculosis in children under 5 years of age. In cervical gland tuberculosis at this period of life 85 per cent. showed the bovine variety, the adult percentage being 18.2. In bone and joint tuberculosis in children under 5 years the bovine proportion was 30.27 per cent., and from 5 to 10 years 23.5 per cent. At the same age 58.3 per cent. of cases of scrofuloderma with tuberculous abscesses under the skin were bovine. In the cases in which the bacillus had obviously entered by the intestinal tract, 80 per cent. were of the bovine form. He did not think the two types could be clinically distinguished.

Mr. G. P. MALE, speaking as a veterinarian, referred to the reduction in the proportion of reactors with improvement in the hygiene of the cattle and cowsheds. In one area 50 per cent. of reactors had been reduced to under 5 per cent. He spoke highly of the work in this direction which had been done by Dr. Stenhouse Williams. The increase in the price of Grado A milk need be only trifling, and reactors which were transferred to other localities should be kept in touch with, and samples of milk taken by inspectors in such districts with unusual frequency. He considered that the Tuberculosis Order should be reintroduced without delay.

Dr. STENHOUSE WILLIAMS gave an account of his work at Reading in raising the standard of hygiene and general cleanliness of dairies in Berkshire, and argued that the health of the populace would be immensely improved by the more general consumption of Grado A milk delivered in sealed bottles. He declared that the unjustly maligned farmer was really most anxious to do his best to maintain a pure milk supply. The speaker said he did not think the American system was suitable to this country. In the United States and Canada milk was transported over immense distances, and temperature extremes were much greater than in this country.

Sir LAYTON BLENKINSOP also spoke from the veterinarian point of view, and, while agreeing with Dr. Rowlands's attitude, thought that he attributed undue importance to vitamin feeding. The use of tuberculin for testing should be in the hands only of qualified veterinarians.

Dr. DAVID NAUARO said that in such a subject as this, with so many interests concerned, it was necessary to look all round the matter and more cautiously. Herds could undoubtedly be freed from tuberculosis, and kept free of the disease for a time; but this meant that the immunity conferred on an immunity against the disease, and this was to the disease of those cattle would be lowered. He was not convinced that it was desirable to free herds from tuberculosis. The taking of small doses of killed tubercle bacilli conferred an immunity against the disease, and this was constantly being done unconsciously. People working in sanatoriums were constantly immunizing themselves by small doses of antigens. The boiling of milk killed the bacilli, and even if a few survived they would not do harm. He agreed that no cow with a gross lesion of the udder should be used for milking, but was that embargo to be placed on all reacting animals? He expressed general agreement with the arguments advanced at the last meeting by Professor Cunnings.

Dr. NATHAN RAW said that the provision of a pure milk supply was one of the most difficult problems of the time. It had been said that a million cows in this country were tuberculous, and that 5 per cent. had gross disease of the udder. Slaughtering infected animals would not help materially, as the young were continually being infected. Attention should be given to immunizing calves as they were born. He favoured the reintroduction of the Tuberculosis Order as soon as possible.

Dr. SCRIFIELD maintained that the only way to keep a herd tuberculosis-free was to breed within the herd, as fresh importations quickly spread the disease. Mr. FREDERICK HODDAY said it was most important that tuberculin should be procurable only by medical men and veterinarians. Mr. HENRY GRAVE urged that the only method of dealing effectively with the problem was to carry out the total eradication of tuberculous cows.

Sir WILLIAM HAMER said that the same methods of cleanliness and hygiene as had been so beneficial in the case of the human being should be applied to cattle, and from that importance of the increasing consumption of Grade A milk, and related some experiences which he had in India.

The following resolution was proposed by Mr. MALE, seconded by Dr. RAW, and carried unanimously:

"That this meeting of the Sections of Epidemiology and State Medicine, Comparative Medicine, and Disease in Children strongly urges the council of the society to press the Government to re-enact the Tuberculosis Order as soon as possible, with the view to reducing the incidence and mortality from tuberculosis in children and to providing a pure milk supply."

## EMPYEMA.

A MEETING of the Section of Medicine of the Royal Academy of Medicine in Ireland was held on February 6th, the President, Dr. F. C. PURSER, in the chair.
